Abstract

A wait-free hierarchy maps object types to levels in \( Z^+ \cup \{\infty\} \), and has the following property: if a type \( T \) is at level \( N \), and \( T' \) is an arbitrary type, then there is a wait-free implementation of an object of type \( T' \), for \( N \) processes, using only registers and objects of type \( T \). The infinite hierarchy defined by Herlihy is an example of a wait-free hierarchy. A wait-free hierarchy is robust if it has the following property: if \( T \) is at level \( N \), and \( S \) is a finite set of types belonging to levels \( N - 1 \) or lower, then there is no wait-free implementation of an object of type \( T \), for \( N \) processes, using any number and any combination of objects belonging to the types in \( S \). Robustness implies that there are no clever ways of combining weak shared objects to obtain stronger ones.

Contrary to what many researchers believe [AGTV92, AR92, Her91a], we prove that Herlihy’s hierarchy is not robust. We then define some natural variants of Herlihy’s hierarchy, which are also infinite wait-free hierarchies. With the exception of one, which is still open, these are not robust either. We conclude with the open question of whether non-trivial robust wait-free hierarchies exist.

---

1 Introduction

A concurrent system consists of asynchronous processes communicating via typed shared objects such as registers, test&sets, and queues. Since any given system supports only a limited set of object types in its hardware, other useful types will need to be implemented in software. Thus, implementing an object of a given type using objects belonging to a given set of types is a fundamental problem. To be useful, implementations must guarantee linearizability [HW90]: concurrent accesses on an implemented object must appear to take effect in some sequential order. One way to ensure linearizability is to implement shared objects using critical sections [CHP71]. This approach however is not fault-tolerant: the crash of a process while in the critical section of an implemented object can permanently prevent the remaining processes from accessing the object. This lack of fault-tolerance led to the concept of wait-free implementations [Lam77]. An implementation is wait-free if every process can complete every operation on the implemented object in a finite number of its own steps, regardless of the execution speeds of the remaining processes. In particular, if object $O$ is built using a wait-free implementation, then the crash of some processes cannot disable the remaining processes from completing their operations on $O$.

How feasible are wait-free implementations? It is known that registers are too weak to implement\(^1\) even a 2-process consensus object, i.e., a consensus object that is accessed by at most two processes [LAA87, CIL87]. Test&sets and 1-bit read-modify-write objects can implement a 2-process consensus object, but not a 3-process consensus object [LAA87]. 3-valued read-modify-write, on the other hand, can implement an $N$-process consensus object, for all $N$. These results indicate that object types differ in their ability to support wait-free synchronization, and that there may be a way of ordering them accordingly. This issue was addressed in a seminal paper by Herlihy [Her88, Her91b]. Following are some important definitions and results in [Her91b].

1. For every object type $T$, an object of type $T$ can be implemented for $N$ processes using only registers and $N$-process consensus objects. This is the universality result of Herlihy.

2. For every $N \geq 1$, $(N+1)$-process consensus object cannot be implemented using just registers and $N$-process consensus objects.

3. The consensus number of a shared object $O$ is the maximum number $N$ such that an $N$-process consensus object can be implemented using just $O$ and (any number of) registers. Define a hierarchy of shared objects such that $O$ is at level $N$ if and only if its consensus number is $N$. This will be referred to as Herlihy's hierarchy.

As an obvious consequence of the universality result, Herlihy's hierarchy has the following important property: if an object $O$ of type $T$ is at level $N$, then for every object type $T'$, an object of type $T'$ can be implemented for $N$ processes using just registers and objects of type $T$. We will call any hierarchy with this property a wait-free hierarchy. Thus, in a

\(^1\)Hereafter "implementation" stands for "wait-free implementation".
wait-free hierarchy such as Herlihy's, if an object \( O \) of type \( T \) is at level \( N \), we can immediately infer that arbitrary wait-free synchronization among \( N \) processes is feasible using just registers and objects of type \( T \). Notice that this definition allows \( O \) to be at level \( N \) even if arbitrary wait-free synchronization among more than \( N \) processes is feasible using registers and objects of the type of \( O \). Thus, the level of an object in a wait-free hierarchy does not reflect the object's full potential; it is only a lower bound on the extent to which the object can support arbitrary wait-free synchronization. To understand the exact potential of objects, we define a \textit{tight} wait-free hierarchy. In such a hierarchy, an object \( O \) is at level \( N \) if \( N \) is the maximum number of processes for which arbitrary wait-free synchronization is feasible using registers and objects of the type of \( O \).

What other properties are important in a hierarchy? We argue below that robustness is one. A hierarchy is \textit{robust} if for every object \( O \), the following holds: if \( O \) is at level \( N \), then it is impossible to implement \( O \) for \( N \) processes using any number and any combination of objects at levels \( N - 1 \) or lower. Robustness guarantees that there are no clever ways of putting weak objects together to implement a strong one. We now present an example to illustrate the significance of robustness in analyzing the power of shared primitives. Consider two systems \( S_1 \) and \( S_2 \). Suppose that \( S_1 \) supports only \textit{registers} and \textit{test&set}s, and \( S_2 \) supports only \textit{registers} with 3-register assignment. Herlihy showed that arbitrary wait-free synchronization is impossible for 3 or more processes in \( S_1 \), and for 5 or more processes in \( S_2 \). What implications do these results have on a third system \( S_3 \) which supports both \textit{test&set}s, and \textit{registers} with 3-register assignment? In particular, can we conclude, based on just the above results, that arbitrary wait-free synchronization among 5 processes is still impossible? We can, provided that Herlihy's hierarchy is robust. Otherwise we cannot. More generally, if Herlihy's hierarchy is robust, the consensus number of a set of objects, belonging (possibly) to different types, is just the maximum of the consensus numbers of the individual objects in the set. Thus, robustness reduces the difficult problem of analyzing the power of a combination of shared objects to the simpler problem of analyzing the power of the individual objects. On the other hand, if robust wait-free hierarchies do not exist, then there is a possibility of combining weak objects to implement strong ones. In particular, it opens up the possibility of implementing universal objects from non-universal objects! Thus, from a pragmatic point of view, it would also be interesting to prove that robust wait-free hierarchies do not exist.

Is Herlihy's hierarchy robust? A study of this question with respect to common object types, such as \textit{register}, \textit{test&set}, \textit{fetch&add}, \textit{queue}, \textit{compare&swap}, and \textit{sticky-bit}, does not present any evidence to the contrary. In fact, many prominent researchers have attributed robustness to Herlihy's hierarchy [AGTV92, AR92, Her91a].\footnote{AGTV92 states "An object has a consensus number \( k \) if \( k \) is the maximum number of processes for which the object can be used to solve the consensus problem. Thus objects with higher consensus number cannot be deterministically implemented by employing objects with lower consensus numbers."}

[AR92] states "In fact, Herlihy [Her88] describes a full hierarchy of atomicity assumptions, and proves that atoms of a higher class cannot be implemented by those of a lower class, in a wait-free fashion in the deterministic setting."

[Her91a] states "Elsewhere [17, 15], we have shown that any object \( X \) can be assigned a consensus number, which is the largest number of processes (possibly infinite) that can achieve consensus asynchronously [13] by
is not robust. More specifically, we present an object type $T_{sp}$ with the property that $k$
objects of this type, together with registers, can implement a $(k+1)$-process consensus
object, but not a $(k+2)$-process consensus object. In particular, one $T_{sp}$ object, with
registers, can implement a 2-process consensus object, but not a 3-process consensus object.
Thus, by definition, a $T_{sp}$ object has a consensus number of 2, and is consequently at
level 2 in Herlihy's hierarchy. However, since multiple $T_{sp}$ objects, with registers, can
implement a consensus object for arbitrarily large number of processes, it follows from
Herlihy's universality result that for all types $T$ and all $N$, an object of type $T$ can be
implemented for $N$ processes using just registers and $T_{sp}$ objects. Together with the fact
that a $T_{sp}$ object is at level 2, this implies that Herlihy's wait-free hierarchy is not robust.

Does there exist a robust wait-free hierarchy? We do not know the answer yet. However,
we define three natural variants of Herlihy's hierarchy, which are also infinite wait-free hier-
archies. We prove that two of these are not robust. The third hierarchy, whose robustness
is still open, has the following property: if it is not robust, then there is no robust wait-free
hierarchy. We believe that resolving the robustness of this hierarchy is an important open
problem in wait-free synchronization.

This paper is the first to formalize and study robustness. The technical arguments
involved in proving the impossibility result that $k$ $T_{sp}$ objects cannot implement a $(k+2)$-
process consensus object are novel. Traditional bivalency arguments are inadequate to prove
such lower bounds.

2 Informal model

A concurrent system consists of processes and shared objects. We write $(P_1, \ldots, P_n; O_1, \ldots, O_m)$
to denote a concurrent system consisting of processes $P_1, \ldots, P_n$ and shared objects $O_1, \ldots, O_m$.
Besides a unique name, every object has two attributes: a type and a positive integer which
denotes the maximum number of processes which may apply operations on that object.
We say that $O$ is an $N$-process object if $N$ is the maximum number of processes which
may apply operations on $O$. The type specifies the behavior of the object when operations
are applied sequentially, without overlap. More precisely, an object type $T$ is a tuple $(OP, RES, G)$,
where $OP$ and $RES$ are sets of operations and responses respectively, and $G$ is a
directed finite or infinite multi-graph in which each edge has a label of the form $(op, res)$
where $op \in OP$ and $res \in RES$. We refer to $G$ as the sequential specification of $T$, and the
vertices of $G$ as the states of $T$. Intuitively, if there is an edge, labeled $(op, res)$, from state
$\sigma$ to state $\sigma'$, it means that applying the operation $op$ to an object in state $\sigma$ may change
the state to $\sigma'$ and return the response $res$.

Applying operations to a shared $X$. It is impossible to construct a non-blocking implementation of any object
with consensus number $n$ from objects with lower consensus numbers in a system of $n$ or more processes,
although any object with consensus number $n$ is universal (it supports a wait-free implementation of any
other object) in a system of $n$ or fewer processes."

"In proving this, we show the following result which is interesting in its own right. There exist two types
such that (i) Even 2-process consensus cannot be solved using objects of either type, and (ii) $N$-process
consensus (for all $N$) can be solved using the two types of objects together.
A sequence \( S = (op_1, res_1), (op_2, res_2), \ldots, (op_i, res_i) \) is legal from state \( \sigma \) of \( T \) if there is a path labeled \( S \) in \( G \) from the state \( \sigma \). \( T \) is deterministic if for every state \( \sigma \) of \( T \) and every operation \( op \in OP \), there is at most one edge from \( \sigma \) labeled \( (op, res) \) (for some \( res \in RES \)). \( T \) is non-deterministic otherwise. \( T \) is total if for every state \( \sigma \) of \( T \) and every operation \( op \in OP \), there is at least one edge from \( \sigma \) labeled \( (op, res) \) (for some \( res \in RES \)). In this paper, we restrict our attention to total types.

An \( N \)-process object \( O \) of type \( T \) supports the set of procedures \( \text{Apply}(P, op, O) \), for all \( 1 \leq i \leq N \) and \( op \in OP(T) \). A process \( P \) invokes operation \( op \) on object \( O \) by calling \( \text{Apply}(P, op, O) \), and executes the operation by executing this procedure. The operation completes when the procedure terminates. The response for an operation is the value returned by the procedure. We denote the event of \( P \) invoking operation \( op \) on \( O \) by \( \text{inv}(P, op, O) \), and the event of \( O \) returning a response \( v \) to \( P \) by \( \text{resp}(P, v, O) \).

The type of an object, by itself, is not sufficient to characterize the behavior of the object in the presence of concurrent operations. To characterize such behavior, we use the concept of linearizability [HW90]. Roughly speaking, linearizability requires every operation execution to appear to take effect instantaneously at some point in time between its invocation and response. We make it more precise below.

Consider a concurrent system \( S = (P_1, P_2, \ldots, P_n; O_1, O_2, \ldots, O_m) \). A configuration of \( S \) is a tuple consisting of the states of the processes \( P_1, \ldots, P_n \) and the states of the objects \( O_1, \ldots, O_m \). An execution \( E \) of \( S \) is a sequence \( C_0, e_0, C_1, e_1, C_2, e_2, \ldots \), where \( C_i \)'s are configurations of \( S \), \( C_0 \) is the initial configuration, \( e_i \)'s are events, and \( C_{i+1} \) is the configuration that results when event \( e_i \) occurs in configuration \( C_i \). The history in \( E \) is the subsequence of events in \( E \). The history of object \( O \) in \( E \) is the subsequence of events of \( O \) in \( E \). If \( e \) and \( e' \) are two events in a history \( H \), we write \( e <_H e' \) if \( e \) is before \( e' \) in \( H \). A complete operation in \( H \) is a pair of events in \( H \) — an invocation and its matching response. An incomplete operation in \( H \) is an invocation that has no matching response. \( H \) is complete if it has no incomplete operations. If \( op \) and \( op' \) are two operations in \( H \), we write \( op <_H op' \) if the response of \( op \) is before the invocation of \( op' \) in \( H \). Two operations \( op \) and \( op' \) are concurrent if neither \( op <_H op' \) nor \( op' <_H op \). \( H \) is sequential if it has no concurrent operations.

Let \( H \) be a history of object \( O \). A linearization of \( H \) is a complete sequential history \( S \) with the following properties:

1. \( S \) includes every complete operation in \( H \).
2. Let \( \text{inv}(P_i, op, O) \) be an invocation in \( H \) with no matching response (and is thus an incomplete operation). Then, either \( S \) does not include this incomplete operation or \( S \) includes a complete operation \( (\text{inv}(P_i, op, O), \text{resp}(P_i, v, O)) \) for some \( v \).

Intuitively, this captures the notion that some incomplete operations in \( H \) had a "visible" effect, while the others did not.
3. \( S \) includes no operations other than the ones mentioned in 1 or 2.
4. For all operations \( op, op' \) in \( S \), if \( op <_H op' \) then \( op <_S op' \).
Thus, the order of non-overlapping operations in \( H \) is preserved in \( S \).

Notice that a given history may have several linearizations. A history \( H \) of object \( O \) is linearizable with respect to type \( T \), initialized to state \( \sigma \), if \( H \) has a linearization which is legal from state \( \sigma \) of \( T \).

Processes are asynchronous: there are no bounds on the relative speeds of processes. Furthermore, a process may crash: a process may stop at an arbitrary point in an execution and never take any steps thereafter. A process is correct in an execution \( E \) if it does not crash in \( E \). We assume that every correct process has an infinite number of events in an infinite execution. An object \( O \) is wait-free in an execution \( E \) if either (i) \( E \) is finite, or (ii) every invocation on \( O \) from a process that does not crash in \( E \) has a matching response.

Let \( T \) be an object type and \( L = (T_1, T_2, \ldots) \) be a (possibly infinite) list of (not necessarily distinct) object types. Let \( \Sigma = (\sigma_1, \sigma_2, \ldots) \) be a list where \( \sigma_i \) is a state of type \( T_i \). An implementation of \( T \), initialized to state \( \sigma \), from \( (L, \Sigma) \) for \( N \) processes is a function \( M(O_1, O_2, \ldots) \) such that if \( O_1, O_2, \ldots \) are \( N \)-process objects of type \( T_1, T_2, \ldots \), initialized to states \( \sigma_1, \sigma_2, \ldots \), respectively, then \( O = M(O_1, O_2, \ldots) \) is an \( N \)-process object of type \( T \), initialized to \( \sigma \). Intuitively, \( M(O_1, O_2, \ldots) \) returns a set of procedures \( \text{App}(P, op, O) \), for \( 1 \leq i \leq N \) and \( op \in OP(T) \). \( \text{App}(P_i, op, O) \) specifies how process \( P_i \) should "simulate" the operation \( op \) on \( O \) in terms of operations on \( O_1, O_2, \ldots \). We say \( O \) is a derived object of the implementation \( M \), and \( O_1, O_2, \ldots, O_n \) are the base objects of \( O \).

We say that \( M \) is an implementation of \( T \), initialized to state \( \sigma \), from a set \( S \) of types for \( N \) processes if there is a list \( L = (T_1, T_2, \ldots) \) of types and a list \( \Sigma = (\sigma_1, \sigma_2, \ldots) \) of states such that \( T_i \in S \), \( \sigma_i \) is a state of \( T_i \), and \( M \) is an implementation of \( T \), initialized to \( \sigma \), from \( (L, \Sigma) \) for \( N \) processes. We say that a type \( T \) has an implementation from a set \( S \) of types for \( N \) processes if for every state \( \sigma \) of \( T \), there is an implementation of \( T \), initialized to \( \sigma \), from \( S \) for \( N \) processes.

An implementation is wait-free if it has the following property: if all base objects are wait-free in an execution \( E \), then the derived object is wait-free in \( E \). Hereafter when we write "implementation", it stands for "wait-free implementation".

We now define consensus and register — two object types that appear frequently in this paper. Type consensus supports two operations: \( \text{propose}(0) \) and \( \text{propose}(1) \). The sequential specification of consensus is in Figure 1. From the specification, it is clear that a consensus object \( O \) has the following properties: (i) If \( O \) returns a response \( v \), then there is an invocation of \( \text{propose}(v) \) preceding this response, and (ii) \( O \) returns the same response to all operations. These are known as the validity and agreement properties, respectively, of a consensus object. Sometimes we refer to the consensus problem for processes \( P_1, P_2, \ldots, P_n \). This problem is stated as follows. Each process \( P_i \) is initially given a binary input \( v_i \). Each correct process \( P_i \) must eventually decide a value \( d_i \) such that (i) \( d_i \in \{v_1, v_2, \ldots, v_n\} \), and (ii) \( \forall 1 \leq i, j \leq n : d_i = d_j \). These two conditions are commonly referred to as the validity and agreement requirements of the consensus problem.

Type register supports the operations \{read\} \cup \{write(v)|v \geq 0\}, and has the sequential specification given in Figure 2.
\[ OP = \{ \text{propose}(v) | v \in \{0, 1\} \} \]

Object State:
\[ X \in \{\bot, 0, 1\} \]

\text{propose}(v)
\begin{align*}
\text{if } X = \bot & \text{ then} \\
X & := v \\
& \text{return}(X)
\end{align*}

### 3 Hierarchy Preliminaries

A \textit{hierarchy of shared types} is a function that maps object types to levels in \{1, 2, 3, \ldots\} \cup \{\infty\}. An object type \( T \) is at level \( l \) in hierarchy \( h \) if \( h(T) = l \). A hierarchy is \textit{non-trivial} if it has at least two non-empty levels. An object type \( T \) is \textit{universal for} \( N \) \textit{processes} if for every type \( T' \), there is an implementation of \( T' \) from \( \{T, \text{register}\} \) for \( N \) processes. \( T \) \textit{is universal (for \( \infty \) processes)} if for all \( N, T \) is universal for \( N \) processes. A hierarchy \( h \) is a \textit{wait-free hierarchy} if for all \( T, h(T) = N \) implies that \( T \) is universal for \( N \) processes. Thus, in a wait-free hierarchy, the level of \( T \) is a lower bound on the number of processes for which \( T \) (together with registers) can support arbitrary wait-free synchronization. The following proposition is immediate from the definition.
Proposition 3.1 If $h$ is a wait-free hierarchy, and $h'$ is a hierarchy such that $\forall T : h'(T) \leq h(T)$, then $h'$ is a wait-free hierarchy.

Proposition 3.2 If $h$ is a wait-free hierarchy, then $h(\text{register}) = 1$. Thus, level 1 of any wait-free hierarchy is non-empty.

Proof There exist object types (for example, queue) which have no implementation from register for two or more processes [Her91b]. Thus, register must be at level 1 in any wait-free hierarchy. \qed

From Proposition 3.1, it is clear that there can be “slack” in a wait-free hierarchy. This motivates us to define tightness. A wait-free hierarchy $h$ is tight if for every wait-free hierarchy $h'$ and every type $T$, $h(T) \geq h'(T)$. A wait-free hierarchy is fully-refined if for all levels $k \in \{1, 2, 3, \ldots \} \cup \{\infty\}$, there is some type in level $k$. A wait-free hierarchy $h$ is robust if for every type $T$ and every finite set $S$ of types, if $h(T) = N$ and $\forall T' \in S : h(T') < N$, then there is no implementation of $T$ from $S$ for $N$ processes. The reader should note the difference between tightness and robustness. The trivial wait-free hierarchy which maps every object type to level 1 is obviously robust, but not tight. The wait-free hierarchy $h^r_\infty$ (to be defined soon) is tight, but it is not known whether it is robust.

In the remainder of this section, we define some natural wait-free hierarchies, and highlight some simple properties of these hierarchies. In the following definitions, the subscript indicates whether the definition allows just 1 or many objects of the argument type. The superscript $r$ indicates that the definition allows the use of registers.

1. $h_1(T) =$ maximum number of processes for which a consensus object can be implemented using just a single object of type $T$. If there is no such maximum, then $h_1(T) = \infty$.

2. $h_1^r(T) =$ maximum number of processes for which a consensus object can be implemented using just a single object of type $T$ and any number of registers. If there is no such maximum, then $h_1^r(T) = \infty$.

Notice that this is Herlihy's hierarchy.

3. $h_{\infty}(T) =$ maximum number of processes for which a consensus object can be implemented using any number of objects of type $T$. If there is no such maximum, then $h_{\infty}(T) = \infty$.

4. $h_{\infty}^r(T) =$ maximum number of processes for which a consensus object can be implemented using any number of objects of type $T$ and any number of registers. If there is no such maximum, then $h_{\infty}^r(T) = \infty$.

Proposition 3.3 Each of $h_1, h_1^r, h_{\infty}, h_{\infty}^r$ is a fully-refined wait-free hierarchy.

Proof Herlihy's universality result trivially implies that these are wait-free hierarchies. That these are fully-refined follows from the easy observation that $\forall h \in \{h_1, h_1^r, h_{\infty}, h_{\infty}^r\}$ and
$OP = \{\text{propose}(v) | v \in \{0, 1\}\}$

Object State:

\begin{align*}
X & \in \{\bot, 0, 1\} \\
N & \in \{0, 1, 2, \ldots\}
\end{align*}

\text{propose}(v)

\begin{align*}
N & := N + 1 \\
\text{if } X = \bot \text{ then} \\
\quad X & := v \\
\text{if } N \leq k \text{ then} \\
\quad \text{return}(X) \\
\text{else } & \text{return}(\bot)
\end{align*}

Figure 3: Sequential specification of $k$-cons

$k \in \{1, 2, 3, \ldots\} \cup \{\infty\}, \ h(k\text{-cons}) = k$. (See Figure 3 for the definition of the type $k$-cons.)

\[\square\]

**Proposition 3.4** $h^*_N(T) = N < \infty$ if and only if $T$ is universal for $N$ processes, but not for $N+1$ processes. $h^*_N(T) = \infty$ if and only if $T$ is universal.

**Proposition 3.5** If $h$ is a tight wait-free hierarchy, then $h = h^*_N$. In other words, $h^*_N$ is the unique wait-free hierarchy which is tight.

The hierarchy $h^*_N$ is uniquely important in the study of robust wait-free hierarchies. To formally state this, we need a definition. Let $\sigma = (l_1, l_2, \ldots)$ be a finite/infinite sequence such that $1 = l_1 < l_2 < l_3 \ldots$ and $l_i \in \{1, 2, 3, \ldots\} \cup \{\infty\}$. We say $g$ is a coarsening of hierarchy $h$ with respect to $\sigma$ if, for all object types $T$, we have:

1. If $l_i \leq h(T) < l_{i+1}$, then $g(T) = l_i$.
2. If $l_i \leq h(T)$ and $l_i$ is the last element of $\sigma$, then $g(T) = l_i$.
3. If $h(T) = \infty$ and $\sigma$ is infinite, then $g(T) = \infty$.

Intuitively, levels $l_i \ldots (l_{i+1} - 1)$ in $h$ are lumped into level $l_i$ of $g$, causing levels $(l_i + 1) \ldots (l_{i+1} - 1)$ to be empty in $g$. We say $g$ is a coarsening of a hierarchy $h$ if there is a $\sigma$ of the form $1 = l_1 < l_2 < l_3 \ldots$ such that $g$ is a coarsening of $h$ with respect to $\sigma$. It is obvious that if $h$ is a wait-free hierarchy, so is every coarsening of $h$.

**Theorem 3.1** If $h$ is a robust wait-free hierarchy, then $h$ is a coarsening of $h^*_N$. 

9
Proof Assume that \( h \) is a robust wait-free hierarchy, and is not a coarsening of \( h^r \). Let \( \sigma = (l_1, l_2, \ldots) \), where \( 1 = l_1 < l_2 < l_3 \ldots \) are all the non-empty levels of \( h \). Define \( g \) to be the coarsening of \( h^r \) with respect to \( \sigma \). From our assumption that \( h \) is not a coarsening of \( h^r \), it follows that \( h \neq g \). Thus, there is a type \( T \) such that \( h(T) \neq g(T) \). Let \( m = h(T) \) and \( n = g(T) \). By definition of \( g \), a level \( k \) of \( g \) is non-empty if and only if level \( k \) of \( h \) is non-empty. Together with \( m \neq n \), this implies that there exist types \( T' \) and \( T'' \), each different from \( T \), such that \( g(T') = m \) and \( h(T'') = n \). Since \( m \neq n \), we are left with two cases to consider.

1. \( m < n \).

Since \( g(T) = n \), it follows that \( h^r(T) \geq n \). Thus, by Proposition 3.4, \( T \) is universal for \( n \) processes. In particular, there is an implementation of \( T'' \) from \( \{T, \text{register}\} \) for \( n \) processes. Since \( h(T) = m < n = h(T'') \), \( h \) is not robust. This is a contradiction.

2. \( m > n \).

From the above, \( g(T') = m \). Thus, level \( m \) of \( g \) is not empty. This, together with \( m > n \), implies that \( n \leq h^r(T) < m \). This implies, by Proposition 3.4, that \( T \) is not universal for \( m \) processes. Since \( h(T) = m \), it follows that \( h \) is not a wait-free hierarchy. This is a contradiction.

This completes the proof of the theorem. \( \square \)

What can we say about the robustness of \( h_1, h_1^r, \) and \( h^r \)? This question is addressed by the following proposition.

Proposition 3.6 Let \( h \in \{h_1, h_1^r, h^r\} \). If \( h \neq h^r \), then \( h \) is neither tight nor robust.

Proof Proposition 3.5 implies that \( h \) is not tight. Theorem 3.1 and Proposition 3.3 imply that \( h \) is not robust. \( \square \)

Does one of \( h_1, h_1^r, \) and \( h^r \) define the same hierarchy as \( h^r \)? The answer is not easy. For instance, \( h_1^r \) differs from \( h^r \) if and only if there is a type such that multiple objects of this type (together with registers) can solve consensus among a larger number of processes than a single object (together with registers) can. Does such a type exist? No common object type exhibits such a property and, hence, it is a non-trivial question. Similarly, \( h^r \) differs from \( h_1^r \) if and only if there is a type such that the use of registers increases the number of processes for which consensus can be solved using objects of this type. Again, common object types do not exhibit this property, making it difficult to answer whether such types exist.

In the rest of the paper, we prove that each of \( h_1, h_1^r, \) and \( h^r \) differs from \( h^r \). Thus, none of \( h_1, h_1^r, \) and \( h^r \) is robust. In particular, \( h_1^r \), which is the same as Herlihy's wait-free hierarchy, is not robust. Unfortunately, we do not yet know whether \( h^r \) or some coarsening of it is robust. This is an important open question. We hope that the ideas employed in this paper would provide useful insights.
4 On the robustness of $h_1^r$ (Herlihy’s hierarchy)

The main result of this section is that $h_1^r$ is not robust. We prove this result by presenting an object type $T_{sp}$ with the following property: $n$ $T_{sp}$ objects, together with registers, can implement a consensus object for $n + 1$ processes, but not for $n + 2$ processes. This implies $h_1^r(T_{sp}) = 2$ and $h_1^r(T_{sp}) = \infty$. Thus, $h_1^r \not= h_1^n$, and by Proposition 3.6, $h_1^r$ is not robust.

Consider the object type $T_{sticky}$ in Figure 4. It supports two operations, $L$-op and $R$-op, and responds with either $L$-first or $R$-first. If $L$-op is applied on a $T_{sticky}$ object $O$, initialized to state $S_L$, $O$ changes state to $S_L$ and returns $L$-first as the response. Furthermore, $O$ returns $L$-first to all subsequent operations, reflecting the fact that $L$-op was the first operation applied on $O$. The behavior is symmetric if, instead of $L$-op, $R$-op was the first operation applied on $O$. In essence, the first operation “sticks” to $O$ and determines the response for all operations. Notice that $T_{sticky}$ is similar to the consensus [Her91b] and sticky-bit [Plo89] object types.

Now consider the type $T_{sp}$, a variant of $T_{sticky}$, shown in Figure 5. $T_{sp}$ lacks the symmetry of $T_{sticky}$: If $R$-op is applied on a $T_{sp}$ object $O$, initialized to $S_L$, $R$-op sticks to $O$ as before. However, as soon as $R$-op is applied for the second time, it “unsticks” and $O$ starts behaving as though it had been stuck with $L$-op all along. The following is a trivial consequence of the definition of $T_{sp}$.

**Lemma 4.1** Let $O$ be an object of type $T_{sp}$ initialized to $S_L$. Let $E$ be an execution in which $R$-op is applied at most once on $O$. Then, the following statements are true in $E$.

1. If $r_1$ and $r_2$ are the responses to any two operations on $O$, then $r_1 = r_2$.
2. If $O$ returns a response $D$-first ($D \in \{L, R\}$), then an invocation of $D$-op precedes this response.

4.1 Implementing consensus from $\{T_{sp}, \text{register}\}$ — upper bound

In this section, we show how to implement a consensus object for $n$ processes using $(n - 1)$ $T_{sp}$ objects and $2(n - 1)$ registers. Our implementation is recursive. Let $\mathcal{I}_j$ denote the
Figure 5: Object type $T_{sp}$

$O_{n-1}$: consensus object for $P_1, P_2, \ldots, P_{n-1}$, derived from $I_{n-1}$
$O_{sp}$: $T_{sp}$ object, initialized to $S_\perp$
$L, R$: binary registers

![Diagram showing the object type $T_{sp}$]

Figure 6: Implementing consensus with $T_{sp}$ and register

Apply($P_i$, propose $v_i$, $O_n$) (for $1 \leq i \leq n-1$)
1. $L := \text{Apply}(P_i, \text{propose } v_i, O_{n-1})$
2. if Apply($P_i$, L-op, $O_{sp}$) = L-first
   3. return($L$)
   4. else return($R$)

Apply($P_n$, propose $v_n$, $O_n$)
1. $R := v_n$
2. if Apply($P_n$, R-op, $O_{sp}$) = L-first
   3. return($L$)
   4. else return($R$)

Implementation of consensus from $\{T_{sp}, \text{register}\}$ for processes $P_1, P_2, \ldots, P_j$. The base case is to derive $I_1$, implementation of consensus for the single process $P_1$, and is trivial: if $O_1$ is a derived object of $I_1$, Apply($P_1$, propose $v_1$, $O_1$) simply returns $v_1$. The recursive step of deriving $I_n$ from $I_{n-1}$ is presented in Figure 6.

Lemma 4.2 The implementation $I_n$ in Figure 6 is a correct implementation of consensus from $\{T_{sp}, \text{register}\}$ for processes $P_1, P_2, \ldots, P_n$. $I_n$ requires $(n - 1)$ objects of type $T_{sp}$ and $2(n - 1)$ registers.

Proof We prove the correctness of $I_n$ by induction. The following is the induction hypothesis: for $1 \leq j \leq n - 1$, $I_j$ is a correct implementation of consensus for processes $P_1, P_2, \ldots, P_j$. The base case, namely, that $I_1$ (described above) is a correct implementation of consensus for $P_1$, is obvious. The induction step is proved through several simple
claims. Let $O_n$ be a derived object of $T_n$. Consider an execution $E$ of the concurrent system $(P_1, P_2, \ldots, P_n, O_n)$. Assume that each $P_i$ executes $Apply(P_i, propose v_i, O_n)$ at most once in $E$.

We make the following claims about $E$. The proof of each claim follows its statement.

**C1.** For $D \in \{L, R\}$, the following holds:

1. Every process that writes the register $D$, writes the same value $V$ in $D$.
2. If $D = L$, $V \in \{v_1, v_2, \ldots, v_{n-1}\}$. Otherwise, $V = v_n$.

For $D = R$, the claim is obvious since only $P_n$ writes $R$. For $D = L$, the claim follows from the agreement and validity properties of $O_{n-1}$.

**C2.** Some process completes a write on $D$ before any process receives the response $D$-first from $O_{sp}$.

By Lemma 4.1, some process, say $P_k$, invokes $D$-op before any process receives the response $D$-first. By the implementation, this process $P_k$ will have completed a write on the register $D$ before invoking $D$-op on $O_{sp}$.

Consider, for arbitrary $i,j$ and $i \neq j$, the executions of $Apply(P_i, propose v_i, O_n)$ and $Apply(P_j, propose v_j, O_n)$ in $E$. By Lemma 4.1, the responses received by $P_i$ and $P_j$ from $O_{sp}$ (in Statement 2 of their respective executions) are the same. Let $D$-first be this response (for some $D \in \{L, R\}$). Thus, in Statement 3, both $Apply(P_i, propose v_i, O_n)$ and $Apply(P_j, propose v_j, O_n)$ read and return the value in the register $D$. From Claims C2 and C1, it follows that both $Apply(P_i, propose v_i, O_n)$ and $Apply(P_j, propose v_j, O_n)$ read the same value $V$ in $D$ and that $V \in \{v_1, v_2, \ldots, v_n\}$. Thus, the value returned by both $Apply(P_i, propose v_i, O_n)$ and $Apply(P_j, propose v_j, O_n)$ is the same and is from $\{v_1, v_2, \ldots, v_n\}$. It is obvious that the implementation is wait-free. Hence the lemma. \qed

**Corollary 4.1** $h^*(T_{sp}) = \infty$.

### 4.2 Implementing consensus from $\{T_{sp}, \text{register}\}$ — lower bound

The main technical result of this section states that any solution to $n$-process wait-free consensus using $T_{sp}$ objects and registers requires at least $n - 1$ $T_{sp}$ objects, regardless of how many registers are available. We prove this result by reducing the “1-resilient consensus problem for $n$ processes communicating via registers” to the “wait-free consensus problem for $n$ processes communicating via registers and $(n - 2)$ $T_{sp}$ objects”. The former problem is impossible to solve [LAA87]. Hence the impossibility of the latter. The reduction is based on the novel concept of $k$-trap implementations.

---

4This is not a limitation for the following reason. After $P_i$ executes $Apply(P_i, propose v_i, O_n)$ once, it can record the return value in its local variable. Thereafter, when $P_i$ needs to apply a propose operation on $O_n$, it may simply return the value of this local variable as the response. This strategy works because $O_n$ is a consensus object, and therefore must return the same response to every invocation.

5A protocol is $k$-resilient if it meets the problem specification despite the crash of $k$ or fewer processes.
4.2.1 k-trap implementations

An implementation for processes $P_1, P_2, \ldots, P_n$ is a \textit{k-trap implementation} if every derived object $O$ of the implementation has the following property: in any execution of $(P_1, P_2, \ldots, P_n; O)$, regardless of the relative execution speeds of processes, all but up to $k$ correct processes will be able to eventually complete their operations on $O$. In other words, $O$ appears wait-free to all but up to $k$ correct processes.

We now contrast $k$-trap implementations with the familiar wait-free, non-blocking, and critical-section based implementations. Critical-section based implementations and non-blocking implementations (for $n$ processes) are both $(n-1)$-trap implementations. A critical-section based implementation is $(n-1)$-trap because the crash of a single process in the critical section blocks the remaining $(n-1)$ processes. A non-blocking implementation is $(n-1)$-trap because repeated execution of operations by one process could cause the remaining processes to block. The converse does not hold: an $(n-1)$-trap implementation does not guarantee the properties of either a critical-section based implementation or a non-blocking implementation. To see this, suppose that exactly one process, say $P$, attempts to access the object, and suppose that $P$ is correct. In the case of a critical-section based implementation or a non-blocking implementation, $P$ is guaranteed to complete its operation on the object. But in a $k$-trap implementation ($k \geq 1$), $P$ may block. Finally, note that a 0-trap implementation is the same as a wait-free implementation.

The following lemma establishes the utility of $k$-trap implementations in proving lower-bounds.

\textbf{Lemma 4.3} \textit{Let $T$ be any object type such that for every state $\sigma$ of $T$, there is a 1-trap implementation $T_{\sigma}$ of $T$, initialized to $\sigma$, from register for $n$ processes. Then, any wait-free implementation of consensus from $\{T, \text{register}\}$ for $n$ processes requires at least $n-1$ objects of type $T$ (regardless of how many registers it uses).}

\textbf{Proof} Suppose that the lemma is false, and there is a wait-free implementation $J$ of consensus from $\{T, \text{register}\}$ for $n$ processes such that $J$ requires only $n-2$ objects of type $T$, initialized to states $\sigma_1, \sigma_2, \ldots, \sigma_{n-2}$ of $T$, and $m$ registers (for some $m \geq 0$). Consider the protocol $P$ in Figure 7. Clearly, processes communicate exclusively via registers in protocol $P$. We argue below that $P$ solves the consensus problem for processes $P_1, P_2, \ldots, P_n$ even if (at most) one of the processes may crash. By the impossibility result in [LAA87], such a protocol does not exist. Hence the lemma.

We claim that at most $(n-2)$ processes block on $O$. This follows from the following facts:

1. $n-2$ base objects of $O$ are 1-trap. So at most one process blocks on each of these.
2. No process blocks on the remaining base objects of $O$, the registers $R_1, R_2, \ldots, R_m$.
3. $O$ is derived from a wait-free implementation.
1. For $1 \leq i \leq n - 2$, use $\mathcal{T}_\sigma$, to implement an object $O_i$ of type $T$ initialized to state $\sigma_i$.

2. Use $\mathcal{J}$ to implement a consensus object $\mathcal{O}$ from $O_1, O_2, \ldots, O_{n-2}$ and registers $R_1, R_2, \ldots, R_m$.

3. Let $D$ be a 3-valued register initialized to $\bot$.

4. For $1 \leq i \leq n$, let $v_i$ be the binary input value of process $P_i$ for consensus. Process $P_i$ executes the following procedure. We require that statements 1 and 2 are executed in a fair manner.

\[
\text{cobegin}
\begin{align*}
1. & \quad D := \text{Apply}(P_i, \text{propose } v_i, \mathcal{O}) \\
2. & \quad \text{repeat until } (D \neq \bot). \\
& \quad \text{decide } D
\end{align*}
\text{coend}
\]

Figure 7: 1-resilient consensus protocol $\mathcal{P}$ for $n$ processes

Therefore, if at most one of $P_1, P_2, \ldots, P_n$ crashes, there is still one process, call it $P_k$, that neither crashes nor blocks on $\mathcal{O}$. This process $P_k$ eventually writes the response, call it $V$, returned by $\text{Apply}(P_k, \text{propose } v_k, \mathcal{O})$ in register $D$. Since $\mathcal{O}$ satisfies validity, we have $V \in \{v_1, v_2, \ldots, v_n\}$. Since $\mathcal{O}$ satisfies agreement, no process ever writes a value different from $V$ in register $D$. Since Statements 1 and 2 are executed in a fair manner, every non-crashing process eventually reads $V$ and decides $V$. In other words, $\mathcal{P}$ solves the consensus problem for $P_1, P_2, \ldots, P_n$ even if at most a single process may crash.

\[
\square
\]

4.2.2 1-trap implementation of $T_{sp}$

Recall that $T_{sp}$ has three states - $S_L$, $S_L$, and $S_R$. We now present a 1-trap implementation of $T_{sp}$ initialized to $S_L$, and 0-trap implementations of $T_{sp}$ initialized to $S_L$ or $S_R$. These implementations use only registers as base objects. Thus, by Lemma 4.3, we have the desired lower bound.

A 1-trap implementation of $T_{sp}$, initialized to $S_L$, from register for $n$ processes is presented in Figure 8. This implementation is subtle. We present below an informal and intuitive argument of its correctness before proceeding to give the formal proof. Consider $\mathcal{O}$, a $T_{sp}$ object derived from this implementation. Let $H$ be a history of $\mathcal{O}$, and let $\text{first-op}$ denote the first operation to complete in $H$. There are two cases. Case (1) corresponds to $\text{first-op}$ being an $L$-op operation. Consider the linearization $S$ which includes only the complete operations in $H$ and sequences them in the order of their completion times. Thus,
$R[1...n]$: binary (1-writer, $n$-reader) registers initialized to 0

$Apply(P_i, L\text{-}op, \mathcal{O})$

```plaintext
return(L-first)
```

$Apply(P_i, R\text{-}op, \mathcal{O})$

1. if $(\forall k : R[k] = 0)$ then
2. $R[i] := 1$
3. repeat until $(\exists j < i : R[j] = 1)$
4. return(L-first)

Figure 8: 1-trap implementation of $T_{ap}$, initialized to $S_{\perp}$, from register

$\textit{first-op}$, which is an $L\text{-}op$ operation, becomes the first operation in $S$. Furthermore, the response of every operation in $S$ is $L\text{-}first$ (this is obvious from the implementation). From the sequential specification of $T_{ap}$ in Figure 5, it is obvious that $S$ is legal from the state $S_{\perp}$ of $T_{ap}$. Now consider Case (2), which corresponds to $first-op$ being an $R\text{-}op$ operation. The key observation is that if $first-op$, which is an $R\text{-}op$ operation, completed in $H$, then by our implementation, there must be another $R\text{-}op$ operation, call it $blocked-op$, from a different process which is concurrent with $first-op$ and is blocked. Let us pretend that, although incomplete, $blocked-op$ has indeed taken effect in $H$, and has $R\text{-}first$ for its response. Consider the linearization $S$ which sequences $blocked-op$ first, $first-op$ second, and the remaining complete operations in $H$ in the order of their completion times. ($blocked-op$ can be linearized before $first-op$ since these two operations are concurrent.) Thus the first operation in the linearization $S$ is a $R\text{-}op$ operation with $R\text{-}first$ as the associated response. The second operation in the linearization is also an $R\text{-}op$ operation, and has $L\text{-}first$ as the associated response. The remaining operations in the linearization have $L\text{-}first$ as their response. From the sequential specification of $T_{ap}$ in Figure 5, it is obvious that this linearization $S$ is legal from the state $S_{\perp}$ of $T_{ap}$. Hence the correctness of our implementation. We formalize the above arguments and present a more rigorous proof of correctness below. The proof is based on a series of claims.

**Claim 4.1** The implementation is 1-trap.

**Proof** Clearly, a correct process $P_i$ blocks if and only if the $repeat \cdots until$ loop (Statement 3 of $Apply(P_i, R\text{-}op, \mathcal{O})$) never terminates. By Statement 2, such a $P_i$ will have written the value 1 into $R[i]$.

Suppose that the claim is false, and two correct processes $P_i$ and $P_j$ (assume $j < i$) block on $\mathcal{O}$. It follows that $R[i] = R[j] = 1$ and each of $P_i$ and $P_j$ is caught in the $repeat \cdots until$ loop that never terminates. Process $P_i$ eventually notices that $R[j] = 1$, and since $j < i$, $P_i$ quits the $repeat \cdots until$ loop, and returns $L\text{-}first$. This contradicts the assumption that $P_i$
blocks on \(O\).

The next claim asserts that if a process \(P_i\) successfully completes an \(R\)-op operation on \(O\), then a different process \(P_j\) is already blocked, unable to complete its \(R\)-op operation on \(O\).

**Claim 4.2** Let \(E\) be an execution of \((P_1, P_2, \ldots, P_n; O)\), and \(H\) be the corresponding history. Suppose that \(H\) contains the two events — an invocation \(e_i^{inv} = \text{inv}(P_i, R\text{-op}, O)\) and its matching response \(e_i^{res} = \text{resp}(P_i, L\text{-first}, O)\). Then \(H\) contains an invocation \(e_j^{inv} = \text{inv}(P_j, R\text{-op}, O)\) such that

1. \(e_j^{inv} <_H e_i^{res}\), and
2. \(e_j^{inv}\) has no matching response in \(H\).

**Proof** The proof of this claim is based on the following observations:

**O1.** The predicate \(\exists k : R[k] = 1\) is stable: that is, if it holds in some configuration of an execution, it holds in every subsequent configuration of that execution. Furthermore, this predicate must hold before a response can occur to any invocation of \(R\)-op.

The first part of this observation follows from the fact that once a 1 is written to a register, it is never changed. The second part is obvious from Statements 1 and 2 of the implementation.

**O2.** In \(H\), let \(k\) be the smallest integer such that \(P_k\) has an invocation \(e_k^{inv} = \text{inv}(P_k, R\text{-op}, O)\) and \(P_k\) writes a 1 in \(R[k]\). Then \(e_k^{inv}\) has no matching response in \(H\).

To see this, notice that after writing a 1 in \(R[k]\), \(P_k\) enters the \texttt{repeat} \(\cdots\) \texttt{until} loop. This loop never terminates in \(H\) because of our premise that \(k\) is the smallest integer such that \(P_k\) writes a 1 in \(R[k]\). Thus \(P_k\) does not return from \texttt{Apply}(\(P_k, R\text{-op}, O\)).

**O3.** In \(H\), if a process \(P_k\) writes 1 in \(R[k]\) after an invocation \(e_k^{inv} = \text{inv}(P_k, R\text{-op}, O)\) and before its matching response, then \(e_k^{inv} <_H e_i^{res}\).

Suppose not. Then \(e_i^{res} <_H e_k^{inv}\). After the invocation \(e_k^{inv}\), when \(P_k\) executes Statement 1 of the procedure \texttt{Apply}(\(P_k, R\text{-op}, O\)), the guard \(\forall k : R[k] = 0\) evaluates to \texttt{false} (by \(O1\)). Thus \(P_k\) returns the response \(L\text{-first}\) without writing into \(R[k]\). This contradicts the premise that \(P_k\) writes 1 into \(R[k]\) after the invocation \(e_k^{inv}\) and before its response.

To complete the proof of the claim, let \(S\) be the set of processes that invoke \(R\)-op on \(O\) and write 1 into a register in the execution \(E\). Since \(H\) contains a response event \(e_i^{res}\), by \(O1\), \(S\) is non-empty. Let \(j\) be the smallest integer such that \(P_j \in S\). By \(O2\), \(P_j\)'s invocation \(e_j^{inv}\) of \(R\)-op on \(O\) has no matching response in \(H\). By \(O3\), \(e_j^{inv} <_H e_i^{res}\). Hence the claim.

**Claim 4.3** Let \(E\) be an execution of \((P_1, \ldots, P_n; O)\), and \(H\) be the history of \(O\) in \(E\). \(H\) is linearizable with respect to \(T_{\text{sp}}\), initialized to state \(S_\bot\).
Proof If $H$ has no response events, then the claim is trivial: the empty sequence is a linearization of $H$ and is legal from state $S_\bot$ of $T_{sp}$. Assume, therefore, that $H$ has one or more response events. Let $e_i^{res} = \text{resp}(P_i, L\text{-first}, \mathcal{O})$ be the earliest response in $H$. Let $e_i^{inv}$ be the invocation whose matching response is $e_i^{res}$. There are two cases:

Case 1. $e_i^{inv} = \text{inv}(P_i, L\text{-op}, \mathcal{O})$

This corresponds to the case in which the first operation to complete is an $L$-op operation from process $P_i$. Define a sequential history $S$ as follows:

1. $S$ includes all complete operations in $H$.
2. If two operations $op$ and $op'$ are in $S$, $op <_S op'$ if and only if response of $op$ precedes the response of $op'$ in $H$.

It is obvious that (i) $S$ is a linearization of $H$, and (ii) $S$ is legal from the state $S_\bot$ of $T_{sp}$.

Case 2. $e_i^{inv} = \text{inv}(P_i, R\text{-op}, \mathcal{O})$

This corresponds to the case in which the first operation to complete is an $R$-op from process $P_i$. By Claim 4.2, there is an invocation $e_j^{inv} = \text{inv}(P_j, R\text{-op}, \mathcal{O})$ such that $e_j^{inv} <_H e_i^{res}$ and $e_j^{inv}$ has no matching response in $H$. Define a sequential history $S$ as follows:

1. $S$ includes all complete operations in $H$, and the operation $(e_i^{inv}, e_j^{res})$, where $e_j^{res} = \text{resp}(P_j, R\text{-first}, \mathcal{O})$.
2. The operation $(e_i^{inv}, e_j^{res})$ precedes all other operations in $S$.
3. If $op$ and $op'$ are operations in $S$ different from $(e_i^{inv}, e_j^{res})$, $op <_S op'$ if and only if the response of $op$ precedes the response of $op'$ in $H$.

It is easy to verify that (i) $S$ is a linearization of $H$, and (ii) $S$ is legal from the state $S_\bot$ of $T_{sp}$.

Hence the claim.

\begin{lemma}
Figure 8 presents a 1-trap implementation of $T_{sp}$, initialized to $S_\bot$, from register for processes $P_1, P_2, \ldots, P_n$.
\end{lemma}

\begin{proof}
Follows from Claims 4.1 and 4.3.
\end{proof}

\begin{lemma}
Figure 9 presents a 0-trap (wait-free) implementation of $T_{sp}$, initialized to $S_R$, from register for processes $P_1, P_2, \ldots, P_n$.
\end{lemma}

\begin{proof}
Let $E$ be an execution of $(P_1, P_2, \ldots, P_n; \mathcal{O})$, and let $H_R$ and $H_\mathcal{O}$ be the histories of objects $R$ and $\mathcal{O}$, respectively, in $E$. Let $\Sigma_R$ be a linearization of $H_R$, which is legal from the state 0 of register. For every operation $op \in \Sigma_R$, define $f(op)$ as follows:

18
$R$: binary register initialized to 0

\begin{align*}
\text{Apply}(P_i, L\text{-}op, O) & \quad \text{Apply}(P_i, R\text{-}op, O) \\
\text{if } (R = 0) \text{ then} & \quad R := 1 \\
\quad \text{return}(R\text{-}first) & \quad \text{return}(L\text{-}first) \\
\text{else return}(L\text{-}first) & \\
\end{align*}

Figure 9: 0-trap implementation of $T_{sp}$, initialized to $S_R$, from register

\[\text{if } op = (\text{inv}(P_i, \text{read, } R), \text{resp}(P_i, 0, R)) \text{ then} \]
\[f(op) = (\text{inv}(P_i, L\text{-}op, O), \text{resp}(P_i, R\text{-}first, O))\]
\[\text{else if } op = (\text{inv}(P_i, \text{read, } R), \text{resp}(P_i, 1, R)) \text{ then} \]
\[f(op) = (\text{inv}(P_i, L\text{-}op, O), \text{resp}(P_i, L\text{-}first, O))\]
\[\text{else if } op = (\text{inv}(P_i, \text{write 1, } R), \text{resp}(P_i, \text{ack, } R)) \text{ then} \]
\[f(op) = (\text{inv}(P_i, R\text{-}op, O), \text{resp}(P_i, L\text{-}first, O))\]

Define a sequential history $\Sigma_O$ as follows:

1. For every operation $op \in \Sigma_R$, include $f(op)$ in $\Sigma_O$.
2. If $op, op' \in \Sigma_R$ and $op <_{\Sigma_R} op'$, then $f(op) <_{\Sigma_O} f(op')$.

It is easy to verify that $\Sigma_O$ is a linearization of $H_O$, and is legal from the state $S_R$ of $T_{sp}$.

\begin{lemma}
Figure 10 presents a 0-trap (wait-free) implementation of $T_{sp}$, initialized to $S_L$, from register for processes $P_1, P_2, \ldots, P_n$.
\end{lemma}

\begin{proof}
Obvious.
\end{proof}

\begin{lemma}
Any wait-free implementation of consensus from $\{T_{sp}, \text{register}\}$ for $n$ processes requires at least $n - 1$ objects of type $T_{sp}$.
\end{lemma}

\begin{proof}
Follows from Lemma 4.3, and Claims 4.4, 4.5, and 4.6.
\end{proof}

\begin{corollary}
$h^*_1(T_{sp}) = 2$.
\end{corollary}

\begin{proof}
By Lemma 4.2, $h^*_1(T_{sp}) \geq 2$. By Lemma 4.7, $h^*_1(T_{sp}) \leq 2$. Hence the result.
\end{proof}

return($L$-first) \\

Apply($P_r$, $R$-op, $O$) \\
return($L$-first)

Figure 10: 0-trap implementation of $T_{sp}$, initialized to $S_L$

---

**Theorem 4.1** $h^T_1$ is neither tight nor robust.

**Proof** Follows from Proposition 3.6 and Corollaries 4.1 and 4.2. □

**Theorem 4.2** $h_1$ is neither tight nor robust.

**Proof** From the definitions of $h_1$ and $h^T_1$, it is obvious that, for all types $T$, $h_1(T) \leq h^T_1(T)$. In particular, $h_1(T_{sp}) \leq h^T_1(T_{sp}) = 2 < \infty = h^\infty_1(T_{sp})$. Thus, by Proposition 3.6, $h_1$ is neither tight nor robust. □

---

### 5 On the robustness of $h_m$

The main result of this section is that $h_m$ is not robust. We prove this result by presenting an infinite family $T^k_{nd}$, $k \in \{2, 3, 4, \ldots\} \cup \{\infty\}$, of object types with the following properties:

1. There is an implementation of consensus from $\{T^k_{nd}, \text{register}\}$ for $k$ processes, but not for $k+1$ processes.

2. There is no implementation of consensus from $T^k_{nd}$ for two processes.

Property (1) implies that $h^\infty_m(T^k_{nd}) = k$. Property (2) implies that $h_m(T^k_{nd}) = 1$. Thus, $h_m \neq h^\infty_m$, and by Proposition 3.6, $h_m$ is not robust.\(^6\) This result is significant in the following sense. Registers by themselves are too weak to solve even 2-process consensus. So are $T^\infty_{nd}$ objects. Combining these two types, however, lets us solve consensus among any number of processes!

The object type $T^k_{nd}$ is specified in Figure 11. In this specification, $\text{choose}(S)$ is assumed to choose an element from set $S$ non-deterministically and return it. Notice that $\text{upset}$ and $\text{ahead}[i]$ are stable: once true, they remain true. Similarly, once $\text{decision} \in \{0, 1\}$, it does not change.

---

\(^6\)A single member of the $T^k_{nd}$ family is sufficient to establish that $h_m$ is not robust. The existence of an entire family shows that there is not even a coarsening of $h_m$ which is non-trivial and robust.
S1. $T_{nd}^k$ supports operations in $\{\text{op}(i) | i = \{0, 1\}\} \cup \{\text{give-decision}(i, b) | i \in \{0, 1\}, b \in \{true, false\}\}$.

S2. The response for $\text{op}(0)$ or $\text{op}(1)$ is always $\text{ack}$. The response for $\text{give-decision}(\neg, \neg)$ is either 0 or 1.

S3. The state of $T_{nd}^k$ is represented by the variables $n_0, n_1, n_{gd} : \text{integer}$; $\text{decision} \in \{\perp, 0, 1\}$; $\text{ahead}[0..1], \text{upset} : \text{boolean}$. Informally, $n_0, n_1, n_{gd}$ count the number of executions of $\text{op}(0)$, $\text{op}(1)$, and $\text{give-decision}$, respectively. The variable $\text{ahead}[i]$ is set to $true$ if $n_i > 0$ and $n_i = 0$ when $\text{give-decision}(i, \neg)$ is executed. The variable $\text{upset}$ is set to $true$ if one of the following happens: (i) $\text{op}(1)$ is executed more than once ($\text{op}(0)$ may be executed any number of times without upsetting a $T_{nd}^k$ object); (ii) $\text{give-decision}$ is executed more than $k$ times; (iii) $\text{give-decision}(i, \neg)$ is executed with no prior execution of $\text{op}(i)$; (iv) $\text{give-decision}(i, true)$ is executed with no prior execution of $\text{op}(i)$; (v) $\text{give-decision}(i, false)$ is executed and $\text{ahead}[i] = true$. If upset, a $T_{nd}^k$ object returns 0 or 1 non-deterministically to an invocation of $\text{give-decision}$. If not upset, it sets $\text{decision}$ irrevocably and non-deterministically (if not already set) to 0 or 1 such that $n_{\text{decision}} > 0$, and returns $\text{decision}$. See S5 below for a formal sequential specification of $T_{nd}^k$.

S4. The state of $T_{nd}^k$ corresponding to $(n_0 = n_1 = n_{gd} = 0; \text{decision} = \perp; \text{ahead}[0..1] = \text{upset} = false)$ is known as the fresh state. The states of $T_{nd}^k$ are only those that are reachable from the fresh state by the following specification.

S5. The sequential specification of $T_{nd}^k$ is as follows:

\[
\begin{align*}
\text{op}(i) & \quad \text{/* } i \in \{0, 1\} \text{ */} \\
& \quad \begin{cases} 
 n_i := n_i + 1 \\
 \text{if } n_i > 1 \text{ then } \text{upset} := true \\
 \text{return(ack)} 
\end{cases} \\
\text{give-decision}(i, \text{other-is-ahead}) & \quad \text{/* } i \in \{0, 1\}, \text{ other-is-ahead: boolean */} \\
& \quad \begin{cases} 
 n_{gd} := n_{gd} + 1 \\
 \text{if } (n_i > 0 \wedge n_i = 0) \text{ then } \text{ahead}[i] := true \\
 \text{if } (n_{gd} > k) \vee (n_i = 0) \vee (\text{ahead}[i] \wedge \neg \text{other-is-ahead}) \vee (n_i = 0 \wedge \text{other-is-ahead}) \text{ then } \\
 \text{upset} := true \\
 \text{if upset then} \\
 \quad \text{return(choose(\{0, 1\}))} \\
 \text{else if } \text{decision} = \perp \text{ then} \\
 \quad \text{decision} := \text{choose(\{j|n_j > 0\})} \\
 \text{return(decision)} 
\end{cases}
\end{align*}
\]

Figure 11: Object type $T_{nd}^k$
5.1 consensus from \( \{T_{\text{nd}}^k, \text{register}\} \) — an implementation

In this section, we show, for \( k \in \{2, 3, \ldots \} \cup \{\infty\} \), how to implement a consensus object for \( k \) processes using only \( T_{\text{nd}}^k \) objects and registers. Our implementation is recursive. Let \( T_n^k \) denote the implementation of consensus from \( \{T_{\text{nd}}^k, \text{register}\} \) for processes \( P_1, P_2, \ldots, P_n \). The base case is to derive \( T_0^k \), implementation of consensus for an empty set of processes, and is vacuous. The recursive step of deriving \( T_n^k \) from \( T_{n-1}^k \) is presented in Figure 12.

The implementation \( T_n^k \) works as follows. Processes \( P_1 \ldots P_n \) split into two groups, \( G_0 \) and \( G_1 \). Group \( G_0 \) has \( P_1 \ldots P_{n-1} \), and group \( G_1 \) has just \( P_n \). Processes \( P_1 \ldots P_{n-1} \) do consensus among themselves (recursively) and announce the outcome in \( R[0] \). Process \( P_n \) announces its input value in \( R[1] \). The rest of the protocol resolves which of the two groups is the winner. If \( G_0 \) wins, every process decides the value in \( R[0] \). Similarly, if \( G_1 \) wins, every process decides the value in \( R[1] \). The object \( O_{\text{nd}} \) is used to determine the winner of the two groups. Processes \( P_1 \ldots P_{n-1} \) perform the operation \( \text{op}(0) \) on \( O_{\text{nd}} \). Then they set the register \( R'[0] \) to inform process \( P_n \) that \( \text{op}(0) \) has been executed on \( O_{\text{nd}} \). Process \( P_n \), on the other hand, performs \( \text{op}(1) \) on \( O_{\text{nd}} \), and then sets \( R'[1] \) to inform processes in \( G_0 \) that \( \text{op}(1) \) has been executed. Processes then perform the \text{give-decision} operation. The return value determines the winning group. For this strategy to work correctly, the arguments of the \text{give-decision} operation must be such that the \( O_{\text{nd}} \) object does not get upset. We urge the reader to understand how the registers \( R'[0..1] \) are used to ensure that \( O_{\text{nd}} \) does not get upset. Finally, if \( O_{\text{nd}} \) returns \( v \), a process assumes that the group \( G_v \) won and decides the value in \( R[v] \).

**Lemma 5.1** For \( 1 \leq n \leq k \), the implementation \( T_n^k \) in Figure 12 is a correct implementation of consensus from \( \{T_{\text{nd}}^k, \text{register}\} \) for processes \( P_1, P_2, \ldots, P_n \).

**Proof Sketch** By induction. Assume that \( T_{n-1}^k \) is correct. Let \( O_n \) be a derived object of the implementation in Figure 12. Consider an execution \( E \) of the concurrent system \((P_1, P_2, \ldots, P_n; O_n)\) in which every process \( P_i \) has invoked \( \text{Apply}(P_i, \text{propose } v_i, O_n) \) exactly once, and executed it to completion. The key claim is that \( O_{\text{nd}} \) is not upset in \( E \). This follows from the following simple observations:

1. \( \text{op}(1) \) is executed only once.
2. For \( v \in \{0, 1\} \), \( \text{op}(v) \) is executed before executing \( \text{give-decision}(v, -) \).
3. \( \text{give-decision} \) is executed no more than \( n \) times. Since \( n \leq k \), \( \text{give-decision} \) is executed no more than \( k \) times.
4. Suppose \( \text{op}(v) \) is ahead of \( \text{op}(\overline{v}) \). That is, the operations \( \text{op}(v) \) and then \( \text{give-decision}(v, -) \) are completed before the first invocation of \( \text{op}(\overline{v}) \). Then, the use of the registers \( R'[0..1] \) in the implementation \( T_{n-1}^k \) guarantees that when a process invokes \( \text{give-decision}(\overline{v}, \text{other-ahead}) \), the second parameter, namely, \( \text{other-ahead} \), is true.
**base objects of the implementation** $T^k_n$
- $O_{n-1}$: consensus object for $P_1, P_2, \ldots, P_{n-1}$, derived from $T^k_{n-1}$
- $O_{nd}$: $T^k_{nd}$ object, initialized to the fresh state
- $R[0..1]$: binary registers
- $R'[0..1]$: boolean registers, initialized to false

**local variables of process** $P_i$
- $d_i, \text{winner}_i \in \{0, 1\}$
- $\text{other-ahead}_i$: boolean

```
Apply(P_i, propose v_i, O_n)  (for 1 \leq i \leq n - 1)  
1. d_i := Apply(P_i, propose v_i, O_{n-1})
2. R[0] := d_i
3. Apply(P_i, op(0), O_{nd})
4. R'[0] := true
5. other-ahead_i := R'[1]
6. winner_i :=
   Apply(P_i, give-decision(0, other-ahead_i), O_{nd})
7. return(R[winner_i])

Apply(P_n, propose v_n, O_n)
1. d_n := v_n
2. R[1] := d_n
3. Apply(P_n, op(1), O_{nd})
4. R'[1] := true
5. other-ahead_n := R'[0]
6. winner_n :=
   Apply(P_n, give-decision(1, other-ahead_n), O_{nd})
7. return(R[winner_n])
```

Figure 12: Implementing consensus from $\{T^k_{nd}, \text{register}\}$
5. Suppose no process completes the operation \( \text{op}(v) \) before some process invokes 
\text{give-decision}(\overline{v}, \text{other-ahead}). Then the use of the registers \( R'[0..1] \) in the implementation \( I_{n-1}^k \) guarantees that the second parameter of \text{give-decision}, namely, \text{other-ahead}, is false.

Since \( O_{nd} \) is not upset in \( E \), by the specification of \( T_{nd}^k \), we have:

1. Every \text{give-decision} operation on \( O_{nd} \) returns the same binary response. Let \( \text{winner} \in \{0,1\} \) denote this response.

2. Some process \( P_j \) invokes \( \text{op}(\text{winner}) \) before \( O_{nd} \) returns \text{winner} for the first time to a \text{give-decision} operation.

From the implementation, it is clear that \( P_j \) writes the value \( d_j \) in \( R[\text{winner}] \) before invoking \( \text{op}(\text{winner}) \). Furthermore, once a value is written by a process into a register \( R[0] \) or \( R[1] \), the value of that register never subsequently changes. For \( R[0] \), this follows from the agreement property of \( O_{n-1}^k \), and for \( R[1] \), this follows from the fact that only \( P_n \) writes \( R[1] \) and writes it only once.

The above implies that for all \( i \), \( \text{Apply}(P_i, \text{propose } v_i, O_n) \) returns \( d_j \). Thus, \( O_n \) satisfies agreement. If \( j = n \), then \( d_j = d_n = v_n \), and thus, \( O_n \) satisfies validity. If \( j \neq n \), by the validity of \( O_{n-1} \), \( d_j \in \{v_1, v_2, \ldots, v_{n-1}\} \). Thus, \( O_n \) satisfies validity. It is obvious that the implementation is wait-free. This concludes the proof of correctness of \( I_n^k \). \( \square \)

5.2 consensus from \( \{T_{nd}^k, \text{register}\} \) — an impossibility result

In this section, we prove that \( T_{nd}^k \) objects and registers do not suffice to implement a consensus object for \( k+1 \) processes. This impossibility result follows from a straightforward bivalence argument. The intuition behind why this impossibility result holds for \( k+1 \) processes, but not for \( k \) processes, is as follows. As we have seen, a \( T_{nd}^k \) object supports two kinds of operations: \( \text{op} \) and \text{give-decision}. The operation \( \text{op}(i) \) does not return any useful information to the invoking process. This is due to the fact that the response of \( \text{op}(i) \) is always \text{ack}. The operation \text{give-decision} does return useful information, but only to the first \( k \) invocations of the operation. Thereafter, its response is non-deterministic and hence is not helpful. Thus, \( k \) processes may gain useful information from a \( T_{nd}^k \) object, but \( k+1 \) processes cannot. We now proceed to prove the impossibility result.

Let \( T_{d}^k \) be a deterministic object type whose specification is defined by replacing every expression of the form \( \text{choose}(S) \) in Figure 11 by \( \text{min}(S) \).\(^7\) Thus, \( T_d^k \) is a deterministic restriction of \( T_{nd}^k \). Hence, if a history of an object is linearizable with respect to \( T_{nd}^k \), then it is a fortiori linearizable with respect to \( T_{nd}^k \). We prove below that \( T_{d}^k \) objects and registers do not suffice to implement a consensus object for \( k+1 \) processes. This trivially implies that \( T_{nd}^k \) objects and registers cannot implement a consensus object for \( k+1 \) processes.

\(^7\) \( \text{min}(S) \) is the minimum element in set \( S \).

24
As mentioned, the proof uses a simple bivalency argument. Since bivalency arguments are standard, our definitions and the proof are informal. A configuration $C$ of a concurrent system is \( v \)-valent (for \( v \in \{0,1\} \)) if there is no execution from $C$ in which $\overline{v}$ is decided by some process. In other words, once the system is in configuration $C$, no matter how processes are scheduled, no process decides $\overline{v}$. A configuration is monovalent if it is either 0-valent or 1-valent. A configuration is bivalent if it is not monovalent. If $E$ is a finite execution of a system $S$ started in configuration $C$, $E(C)$ denotes the configuration of $S$ at the end of the execution $E$. For the purposes of this section, a step of a process $P$ consists of invoking an operation on an object $O$, receiving the response from $O$, and making an appropriate change in its state.

Lemma 5.2 For all \( k \in \{2,3,\ldots\} \), there is no implementation of consensus from \( \{T_d^k, \text{register}\} \) for \( k + 1 \) processes.

Proof Assume $T(O_1, O_2, \ldots, O_n)$ is an implementation of consensus from \( \{T_d^k, \text{register}\} \) for processes $P_1, P_2, \ldots, P_{k+1}$. Let $\mathcal{O} = T(O_1, O_2, \ldots, O_n)$. Consider the concurrent system $S = (P_1, P_2, \ldots, P_{k+1}, \mathcal{O})$. Let $C_0$ be the initial configuration of $S$. Assume that in $C_0$, each process $P_i$ is about to execute $\text{Apply}(P_i, \text{propose} \, v_i, \mathcal{O})$. Furthermore, assume that there are $l, m$ (\( 1 \leq l, m \leq k + 1 \)) such that $v_l = 0$ and $v_m = 1$.

When $P_l$ runs by itself from $C_0$, the validity and wait-freedom of $\mathcal{O}$ require that $P_l$ decide $v_l = 0$. Similarly, when $P_m$ runs by itself from $C_0$, it decides $v_m = 0$. Thus, $C_0$ is bivalent. Let $E$ be an execution from $C_0$ such that (1) $C_{\text{crit}} = E(C_0)$ is bivalent, and (2) For all $P_i$, if $P_i$ takes a step from $C_{\text{crit}}$, the resulting configuration is monovalent. Let $S_v$ be the set of processes whose step from $C_{\text{crit}}$ results in a $v$-valent configuration. Since $C_{\text{crit}}$ is bivalent, neither $S_0$ nor $S_1$ is empty. Furthermore, $S_0 \cap S_1 = \emptyset$ and $|S_0 \cup S_1| = k + 1 \geq 3$ (since $k \geq 2$). Without loss of generality, assume that $|S_0| \geq 2$ and $|S_1| \geq 1$. In particular, let $S_0 = \{P_0^0, P_2^0, \ldots, P_r^0\}$ and $S_1 = \{P_1^1, P_2^1, \ldots, P_s^1\}$, where $r \geq 2$ and $s \geq 1$.

By a standard argument, the enabled step of every process in configuration $C_{\text{crit}}$ must be on the same base object $O$ of $\mathcal{O}$. Furthermore, again by a standard argument, $\mathcal{O}$ is not a register. Thus, the enabled step of every process in configuration $C_{\text{crit}}$ is on $O$, an object of type $T_d^k$. Let $s_0^0$ and $s_1^1$ denote the enabled steps of $P_2^0$ and $P_1^1$, respectively, in configuration $C_{\text{crit}}$. Consider the following scenarios $S_0$ and $S_1$, each starting from the configuration $C_{\text{crit}}$.

- In Scenario $S_0$, $P_2^0$ takes the step $s_0^0$. Then, $P_1^1$ takes a step. Let $D_0$ be the resulting configuration. Clearly $D_0$ is a 0-valent configuration.

- In Scenario $S_1$, $P_1^1$ takes the step $s_1^1$. Then, $P_2^0$ takes a step. Let $D_1$ be the resulting configuration. Clearly $D_1$ is a 1-valent configuration.

Processes $P_2^0$ and $P_1^1$ have to distinguish Scenario $S_0$ from Scenario $S_1$, since they must decide 0 in (every extension of) $S_0$, and decide 1 in (every extension of) $S_1$. Observe that unless the operation applied by $P_2^0$ (resp. $P_1^1$) in step $s_2^0$ (resp. $s_1^1$) is a give-decision operation, it must eventually apply a give-decision operation on $O$ in order to distinguish $S_0$ from $S_1$. Thus, we extend Scenarios $S_0$ and $S_1$ as follows:
• If the operation applied by $P^0_2$ on $O$ in step $s^0_2$ is not a \textit{give-decision} operation, run $P^0_2$ (in both scenarios) exactly until $P^0_2$ completes a step in which it applies a \textit{give-decision} operation on $O$.

• If the operation applied by $P^1_1$ on $O$ in step $s^1_1$ is not a \textit{give-decision} operation, run $P^1_1$ (in both scenarios) exactly until $P^1_1$ completes a step in which it applies a \textit{give-decision} operation on $O$.

A process $P \in \{P_1, \ldots, P_{k+1}\} - \{P^0_1, P^0_2, P^1_1\}$ has to distinguish Scenario $S_0$ from Scenario $S_1$, since $P$ must decide 0 in (every extension of) $S_0$, and decide 1 in (every extension of) $S_1$. Observe, however, that $P$ cannot distinguish $S_0$ from $S_1$ until it applies a \textit{give-decision} operation on $O$. Thus, we extend Scenarios $S_0$ and $S_1$ as follows:

• For each $P \in \{P_1, \ldots, P_{k+1}\} - \{P^0_1, P^0_2, P^1_1\}$, run $P$ (in both scenarios) exactly until $P$ completes a step in which it applies a \textit{give-decision} operation on $O$.

We make the following observations: (1) The process $P^0_1$ is in the same state in Scenarios $S_0$ and $S_1$. (2) Every base object except $O$ is in the same state in $S_0$ and $S_1$. (3) In both $S_0$ and $S_1$, a \textit{give-decision} operation is applied on $O$ at least $k$ times (once by each process in $\{P_1, \ldots, P_{k+1}\} - \{P^1_1\}$, in the execution from $C_{crit}$). The second observation, together with the specification of $T^k_{nd}$, implies that every subsequent \textit{give-decision} operation on $O$ returns 0 in either scenario. Extend Scenarios $S_0$ and $S_1$ by letting $P^0_1$ run by itself. By the above observations, $P^0_1$ cannot distinguish whether it is running in $S_0$ or $S_1$. Yet it must decide 0 in $S_0$ and 1 in $S_1$. This is impossible. Hence the lemma.

\textbf{Corollary 5.1} For all $k \in \{2, 3, \ldots\} \cup \{\infty\}$, $h^*(T^k_{nd}) = k$.

\textit{Proof} Follows from Lemmas 5.1 and 5.2. \hfill \Box

5.3 \textbf{$h_\text{nd}$ is not robust}

In this section, we prove that $h_\text{nd}(T^k_{nd}) = 1$. Thus, $h_\text{nd}$ is different from $h^*_{nd}$ and, hence, is not robust. We begin with a simple technical lemma that will be useful in proving $h_\text{nd}(T^k_{nd}) = 1$.

The lemma states that it is trivial to implement $T^k_{nd}$, initialized to any state different from the fresh state. In the following, let $\sigma[v]$ denote the value of state variable $v$ in state $\sigma$.

\textbf{Lemma 5.3} Let $\sigma$ be any state of $T^k_{nd}$ different from the fresh state. Figure 13 is an implementation of $T^k_{nd}$, initialized to $\sigma$, from $\emptyset$.\textsuperscript{8}

\textit{Proof} If $\sigma$ is different from the fresh state, then it is easy to verify that $(\sigma[\text{decision}] \in \{0, 1\}) \lor (\sigma[n_0] > 0) \lor (\sigma[n_1] > 0) \lor \sigma[\text{upset}]$. From this and the specification of $T^k_{nd}$, the correctness of the implementation is obvious. \hfill \Box

\textsuperscript{8}Thus, the implementation requires no base objects, not even registers.
op(i)  
give-decision(i,b)  

return(ack)  
if \sigma[decision] \in \{0, 1\} then  
\quad return(\sigma[decision])  
else if (\sigma[upset] \lor \sigma[n0] > 0) then  
\quad return(0)  
else return(1)

---

Figure 13: Implementing \(T_{nd}^k\), initialized to a non-fresh state \(\sigma\)

The following lemma states that it is impossible to implement a consensus object for two processes using just \(T_{nd}^k\) objects. Intuitively, \(T_{nd}^k\) objects are so weak that a process cannot use these objects to leave its "foot marks" behind. Thus, if a process \(P_0\) runs first, and then a different process \(P_1\) runs, \(P_1\) does not realize that \(P_0\) ran before it started. This can cause \(P_1\) to decide a value which is not consistent with the decision of \(P_0\). The proof below formalizes this argument. The details of the argument are subtle due to the non-determinism of the \(T_{nd}^k\) objects.

**Lemma 5.4** For all \(k \in \{2, 3, \ldots\} \cup \{\infty\}\), \(h_\omega(T_{nd}^k) = 1\).

*Proof* To prove this lemma, we must show that it is impossible to implement a consensus object for two processes using just \(T_{nd}^k\) objects. We show this by contradiction. Let \(I(O_1, O_2, \ldots, O_n)\) be an implementation of consensus from \(T_{nd}^k\) for processes \(P_0\) and \(P_1\), which is resource optimal: i.e., if \(I'\) is another implementation of consensus from \(T_{nd}^k\) for two processes, then \(I'\) requires at least \(n\) base objects. From Lemma 5.3, it follows that every base object of \(I\) is initialized to the fresh state.

Consider a derived consensus object \(O\) of the implementation \(I\). Let \(O_1, O_2, \ldots, O_n\) be the base objects of \(O\). In other words, \(O = I(O_1, O_2, \ldots, O_n)\). In the following, we present two scenarios, \(S_0\) and \(S_1\), which are indistinguishable to \(P_1\), but require \(P_1\) to take different actions.

In Scenario \(S_0\), \(P_0\) invokes \texttt{Apply}(\(P_0\), \texttt{propose} 0, \(O\)) and executes it to completion. (Execution to completion is possible since \(I\) is a wait-free implementation.) Assume that during the execution of \texttt{Apply}(\(P_0\), \texttt{propose} 0, \(O\)), every base object behaves like a \(T_{d}^k\) object. That is, the history of each base object in the execution of \texttt{Apply}(\(P_0\), \texttt{propose} 0, \(O\)) is linearizable with respect to \(T_{d}^k\). We will refer to this as Assumption A1. By the validity property of \(O\), \texttt{Apply}(\(P_0\), \texttt{propose} 0, \(O\)) returns 0. Let \(S\) be the set of base objects which are in the fresh state in Scenario \(S_0\) at the completion of \texttt{Apply}(\(P_0\), \texttt{propose} 0, \(O\)). Continue Scenario \(S_0\), and begin Scenario \(S_1\), by letting \(P_1\) invoke \texttt{Apply}(\(P_1\), \texttt{propose} 1, \(O\)) and run by itself in either scenario. (See Figure 14 for a depiction of Scenarios \(S_0\) and \(S_1\).) Assume that each
base object in $\mathcal{S}$ behaves deterministically, consistent with $T^b_{A1}$, in both scenarios. We will refer to this as Assumption A2. We prove the following statement inductively: the base objects in $\{O_1, O_2, \ldots, O_n\} - \mathcal{S}$ can choose among the non-deterministic alternatives (when applicable) such that for all $i \geq 0$, $P_1$ cannot distinguish $S_0$ from $S_1$ in $i$ steps. The base case for $i = 0$ is trivial. To prove the induction step, assume the hypothesis for $i \leq m$.

Consider the $(m + 1)^{st}$ step. Let $oper$ be the operation that $P_1$ performs in this step in Scenario $S_0$, and let $O$ be the base object on which it performs $oper$. From the induction hypothesis and the fact that the implementation is deterministic, it follows that $P_1$ performs $oper$ on $O$ in its $(m + 1)^{st}$ step in Scenario $S_1$ too.

Suppose $oper \in \{op(0), op(1)\}$. Then, the response is $ack$ in either scenario. Thus, $S_0$ and $S_1$ remain indistinguishable to $P_1$ after $m + 1$ steps. Hence the induction step.

Suppose that $oper$ is $\text{give-decision}(\sim, \sim)$. We make a case analysis to prove the induction step.

Case 0. $O \in \mathcal{S}$

$O$ is fresh in both $S_0$ and $S_1$ just before the invocation of $\text{Apply}(P_1, \text{propose} 1, \mathcal{O})$. For $S_0$, this follows from the definition of $\mathcal{S}$, and for $S_1$, from the fact that every base object is initialized to the fresh state. By Assumption A2, $O$ behaves deterministically (consistent with $T^b_{A2}$) in both scenarios. The above facts, together with induction hypothesis, guarantee that (i) $O$ is in the same state in both scenarios at the end of $m$ steps of $P_1$, and (ii) $O$ returns the same response to $oper$ in both scenarios. Thus, $S_0$ and $S_1$ remain indistinguishable to $P_1$ after $m + 1$ steps. Hence the induction step.
Case 1. Case 0 does not apply and the following holds: In at least one of $S_0$ and $S_1$, $O$ is upset in the first $m + 1$ steps of $P_1$.

Let $S_1$ be a scenario in which $O$ is upset in the first $m + 1$ steps of $P_1$. By the specification of $T^k_{nd}$, $O$ is free to return 0 or 1 to oper in Scenario $S_1$. Suppose that $O$ uses this freedom and returns the same response to oper in $S_1$ as it does in $S_T$. Then $S_0$ and $S_1$ remain indistinguishable to $P_1$ after $m + 1$ steps. Hence the induction step.

Case 2. Neither Case 0 nor Case 1 applies. In other words, $O$ is not fresh in $S_0$ just before the invocation of Apply($P_1$, propose 1, $O$) and, in both $S_0$ and $S_1$, $O$ is not upset at the end of $m + 1$ steps of $P_1$.

We prove the induction step by contradiction. Assume that it is not possible to keep Scenarios $S_0$ and $S_1$ indistinguishable to $P_1$ at the end of $m + 1$ steps. We will refer to this as Assumption A3. We arrive at a contradiction after a series of claims. Let $\sigma^k_0$ and $\sigma^k_1$ denote the state of $O$ at the end of $k$ steps of $P_1$ in Scenarios $S_0$ and $S_1$ respectively.

C1. $\sigma^m[n_{gd}] = 0$. In other words, $P_1$ does not apply a give-decision operation on $O$ in its first $m$ steps.

Suppose that the claim is false. Let $k \leq m$ be the smallest integer such that $\sigma^k_0[n_{gd}] = 1$. That is, give-decision is executed on $O$ for the first time by $P_1$ in its $k^{th}$ step in Scenario $S_1$. Since $O$ is not upset in $S_1$, this implies that $\sigma^k_1[\text{decision}] \in \{0, 1\}$, and this value is returned by $O$ in the $k^{th}$ step of $P_1$ in $S_1$. By inductive hypothesis, the same value $\sigma^k_1[\text{decision}]$ is returned by $O$ in the $k^{th}$ step of $P_1$ even in $S_0$. Since $O$ is not upset in $S_0$, this implies that $\sigma^m_0[\text{decision}] = \sigma^k_1[\text{decision}]$. Since decision is irrevocable, it follows that $\sigma^m_0[\text{decision}] = \sigma^m_0[\text{decision}] = \sigma^m_1[\text{decision}] = \sigma^m_0[\text{decision}] \in \{0, 1\}$. Since $O$ is not upset in either scenario, the responses $\sigma^m_0[\text{decision}]$ and $\sigma^m_1[\text{decision}]$ of $O$ to oper in Scenarios $S_0$ and $S_1$, respectively, are identical. Thus, $S_0$ and $S_1$ remain indistinguishable to $P_1$ after $m + 1$ steps. This contradicts Assumption A3.

C2. There is a $v \in \{0, 1\}$ such that $\sigma^m_0[n_v] > 0$ and $\sigma^m_1[n_v] = 0$. In other words, $P_1$ executes op($v$), but not op($\overline{v}$) in its first $m$ steps in $S_1$.

Suppose $\sigma^m_1[n_0] = \sigma^m_1[n_1] = 0$. Then, by the specification of $T^k_{nd}$, when $P_1$ applies oper $\equiv$ give-decision($-,-$) in the $(m + 1)^{st}$ step in $S_1$, it upsets $O$. This contradicts the case we are considering. Suppose $\sigma^m_0[n_0] > 0$ and $\sigma^m_0[n_1] > 0$. Since $\sigma^m_0[n_{gd}] = 0$ (by C1), by the specification of $T^k_{nd}$, $O$ is free to return either 0 or 1 in $S_1$. Suppose that $O$ uses this freedom and returns the same response to oper in $S_1$ as it does in $S_0$. Then $S_0$ and $S_1$ remain indistinguishable to $P_1$ after $m + 1$ steps. This contradicts Assumption A3.

C3. $P_1$ executes op($v$) on $O$ at least once in its first $m$ steps in $S_0$.

Follows from C2 and the induction hypothesis.

C4. oper $\equiv$ give-decision($v$,false).

Suppose oper $\equiv$ give-decision($\overline{v},-)$ or oper $\equiv$ give-decision($v$,true). Since $\sigma^m_0[n_v] = 0$ (by C2), $O$ will be upset in $S_1$ when oper is invoked in the $(m + 1)^{st}$ step. This contradicts the case we are considering.
C5. $\sigma_{0}^{m}[\text{ahead}[\bar{v}]] = \text{false}$. Suppose $\sigma_{0}^{m}[\text{ahead}[\bar{v}]] = \text{true}$. Then, when $P_{1}$ executes $\text{oper} \equiv \text{give-decision}(v, \text{false})$ (guaranteed by C4) in its $(m + 1)^{st}$ step in $S_{0}$, it upsets $O$. This contradicts the case we are considering.

C6. $v = 1$ implies $\sigma_{0}^{m}[n_{gd}] = 0$. In other words, if $v = 1$, then $P_{0}$ never executed a $\text{give-decision}$ operation on $O$ in $S_{0}$. Suppose $v = 1$ and $P_{0}$ executed $\text{give-decision}(1, -)$ on $O$ in $S_{0}$. Since $O$ is not upset in $S_{0}$, it follows that $P_{0}$ executed $\text{op}(1)$ on $O$ before executing $\text{give-decision}(1, -)$. By C3 and the assumption that $v = 1$, $P_{1}$ executed $\text{op}(1)$ in $S_{0}$. Thus $\text{op}(1)$ was executed at least twice on $O$ in $S_{0}$. By the specification of $T_{nd}^{k}$, $O$ would be upset in $S_{0}$. This contradicts the case we are considering. Suppose $v = 1$ and $P_{0}$ executed $\text{give-decision}(0, -)$ on $O$ in $S_{0}$. Since $O$ is not upset in $S_{0}$, it follows that $P_{0}$ executed $\text{op}(0)$ on $O$ before executing $\text{give-decision}(0, -)$. By C5 and the assumption that $v = 1$, $\sigma_{0}^{m}[\text{ahead}[0]] = \text{false}$. This implies that $P_{0}$ executed $\text{op}(1)$ on $O$ before executing $\text{give-decision}(0, -)$. By C3 and the assumption that $v = 1$, $P_{1}$ executed $\text{op}(1)$ in $S_{0}$. Thus $\text{op}(1)$ was executed at least twice on $O$ in $S_{0}$. By the specification of $T_{nd}^{k}$, $O$ would be upset in $S_{0}$. This contradicts the case we are considering.

C7. $v = 0$. Suppose $v = 1$. Then, we can infer: (1) $\sigma_{0}^{m}[n_{gd}] = 0$ (by C1), (2) $\sigma_{0}^{m}[n_{gd}] = 0$ (by C1, induction hypothesis, and C6), (3) $\sigma_{0}^{m}[n_{1}] > 0$ (by C2), (4) $\sigma_{0}^{m}[n_{1}] > 0$ (by C3). These four facts, together with the specification of $T_{nd}^{k}$, imply that $O$ is free to return 0 to $\text{oper}$ in both $S_{0}$ and $S_{1}$. Suppose that $O$ does this. Then $S_{0}$ and $S_{1}$ remain indistinguishable to $P_{1}$ after $m + 1$ steps. This contradicts Assumption A3.

C8. $O$ returns 0 to $\text{oper}$ (in the $(m + 1)^{st}$ step of $P_{1}$) in Scenario $S_{1}$. C2 and C6 imply that $\sigma_{0}^{m}[n_{0}] > 0$ and $\sigma_{0}^{m}[n_{1}] = 0$. Further, by the case we are considering, $O$ is not upset in the first $m + 1$ steps of $P_{1}$ in Scenario $S_{1}$. The above facts imply that the only legal value that $O$ can return to $\text{oper}$ is 0.

C9. If $P_{0}$ executed $\text{give-decision}(1, -)$ on $O$ (in $S_{0}$), it did so only after executing $\text{op}(0)$ on $O$. Suppose $P_{0}$ executed $\text{give-decision}(1, -)$ on $O$ (in $S_{0}$). Since $O$ is not upset in $S_{0}$, this implies that $P_{0}$ executed $\text{op}(1)$ on $O$ before executing $\text{give-decision}(1, -)$. If $P_{0}$ did not execute $\text{op}(0)$ before executing $\text{give-decision}(1, -)$, then the execution of $\text{give-decision}(0, -)$ would set $\text{ahead}[1]$ to true. This, together with the fact that $\text{ahead}[0]$ is stable, implies that $\sigma_{0}^{m}[\text{ahead}[1]] = \text{true}$. This contradicts the conjunction of C5 and C7.

C10. Every execution of the operation $\text{give-decision}(-, -)$ on $O$ by $P_{0}$ in Scenario $S_{0}$ returns the response 0. Consider the earliest execution $e$ of $\text{give-decision}(w, -)$ on $O$ by $P_{0}$ in $S_{0}$. If $w = 1$, C9 implies that $P_{0}$ executes $\text{op}(0)$ before $e$. If $w = 0$, the fact that $O$ is not upset in $S_{0}$ implies that $P_{0}$ executes $\text{op}(0)$ before $e$. Thus, we conclude that
$P_0$ executes op(0) before $e$. This, together with Assumption A1, implies that $e$ returns 0. From this and the fact that $O$ is not upset in $S_0$, it follows that every execution of give-decision($-,-$) on $O$ in $S_0$ returns the response 0.

C11. $P_0$ never executes give-decision($-,-$) on $O$ (in $S_0$).

Suppose that the claim is false. Then, from C10 and the fact that $O$ is not upset in $S_0$, it follows that $O$ returns 0 to oper in the $(m + 1)^{st}$ step of $P_1$ in Scenario $S_0$. Thus, by C8, $S_0$ and $S_1$ remain indistinguishable to $P_1$ after $m + 1$ steps. This contradicts Assumption A3.

We have: (1) $\sigma_1^n[n_0] > 0$. This follows from C3 and C7. (2) $\sigma_0^n[n_0] > 0$. This follows from (1) and induction hypothesis. (3) $\sigma_0^n[n_{gd}] = 0$. This follows from C1, induction hypothesis, and C11. From (2), (3), and the specification of $T_{nd}$, it is clear that $O$ is free to return 0 to oper (in the $(m + 1)^{st}$ step of $P_1$) in Scenario $S_0$. Suppose that it does. Then, by C8, $S_0$ and $S_1$ remain indistinguishable to $P_1$ after $m + 1$ steps. This contradicts Assumption A3. Hence the induction step.

This completes the proof of the induction step.

Since $T$ is a wait-free implementation, Apply($P_1$, propose 1, $O$) terminates in $S_0$ after a finite number of steps, returning some value $val \in \{0,1\}$. Since $S_1$ is indistinguishable to $P_1$ from $S_0$, Apply($P_1$, propose 1, $O$) terminates in $S_1$ after the same number of steps, also returning $val$. If $val = 0$, validity of consensus is violated in $S_1$. If $val = 1$, agreement of consensus is violated in $S_0$. Thus, $T$ is not a correct implementation, a contradiction. □

**Theorem 5.1** $h_{n}$ is neither tight nor robust.

**Proof** Follows from Proposition 3.6, Corollary 5.1, and Lemma 5.4. □

### 6 Conclusion

It is well known that shared primitives, depending on their type, vary widely in their ability to support inter-process synchronization. Recent research focused on analyzing the power of individual primitives. In this paper, we ask whether, from our understanding of the power of the individual primitives, we can infer the power of a set of primitives. For instance, is it impossible to implement a universal primitive from non-universal primitives? The answer is not clear. It is conceivable that clever protocols for such implementations exist. Besides being of theoretical interest, these issues have implications to multi-processor architectures. To make a systematic study of these issues possible, we define the property of robustness for wait-free hierarchies. Contrary to popular belief, we show that Herlihy's wait-free hierarchy is not robust. We also show that some natural variants of Herlihy's hierarchy are also not robust. This raises the obvious question of whether there is a non-trivial robust wait-free hierarchy at all. We do not know the answer yet. However, we observe that such a hierarchy, if it exists, is either $h_{n}$ or some coarsening of it. Thus, further research on the structure
of $h^*$ is essential to resolving this open question. As explained in the paper, the answer to this question, regardless of whether it is affirmative or negative, has useful implications. We close with the conjecture that $h^*$ is not robust.

Acknowledgement

I had innumerable discussions with my advisor Sam Toueg on this subject. They were very helpful in crystallizing my ideas, and in discovering some of these results. The “swap object” that Jon Kleinberg and Sendhil Mullainathan showed me helped me discover $T_{sp}$. I am grateful to Sam, Jon, and Sendhil for sharing their insights with me. I thank Tushar Chandra for reading parts of this paper and providing helpful comments. Aparna helped me with typing. Little Sucharita never complained the travel between home and school, no matter what time of the night and how cold.
