Abstract

Some problems in the dynamics of sliding of planar rigid bodies are treated by geometric methods based on the limit surface description of friction (Goyal, Ruina, Papadopoulos [1990]). The problems we consider, where the normal force is known a priori, have unique solutions although the friction force (and torque) may be a discontinuous function of the direction of motion. When a freely sliding object comes to rest it always does so with one of several definite ratios of translation to rotation. These special generalized velocity directions, termed eigen-directions, depend on the friction law used, the contact pressure distribution and the mass distribution. The eigen-directions correspond to local extrema of the generalized frictional load $|P|$ on the limit surface, i.e. to directions in load space where $P$ is parallel to the generalized motion direction $q$. For most objects, if the radius of gyration is sufficiently larger than the radius of the contact region final motion is always pure rotation about the center of mass; if the mass distribution is sufficiently central the final motion is a pure translation. A simple model of a car with locked rear wheels shows the effect of speed and orientation on skid stability at finite speeds. Sliders have a propensity to rotate about points of support.

Introduction

Ishlinskii, Sokolov, and Chernousko [1981] and (apparently independently) Vøjenli and Eriksen [1985] noticed the special motions of a sliding ring and a sliding disk as they come to rest during free sliding on a horizontal plane under the influence of gravity and dry friction. In particular a rigid ring, with all contact pressure and mass concentrated on a circle, ends up just before stopping, by rotating about a point on the ring no matter what the initial condition (unless the initial condition is pure rotation or pure translation). Similarly, a circular disk with uniform pressure and mass distribution, comes to rest by rotation about a point 0.653 of the disk radius from the center, irrespective of the initial condition (again, unless the initial condition is a pure rotation, or a pure translation). Additionally, Wittenburg [1970] and Ishlinskii, Sokolov, and Chernousko [1981] find that a bar with symmetric point masses and supports at its ends, stops with rotation about one of its points of support for all initial conditions, except pure rotation about its center or pure translation. The general tendency of objects to rotate about points of support has also been noted by earlier investigators, such as Jellett [1872], Prescott [1923], and MacMillan [1936].

These results led us to look into the dynamics of sliders. The limit surface description from Goyal [1989] and Goyal, Ruina, Papadopoulos [1989, 1990] allows us to simply reproduce the results named above as well as to generalize them. Other aspects of free sliding motion are also illuminated with the limit surface.

The order of the material presented in the rest of the paper is as follows. The equations of motion, for a rigid planar slider subject to applied loads and friction are reviewed. The uniqueness of dynamic solutions is then discussed and contrasted to the non-uniqueness of quasistatic solutions. That final motions are eigendirections, is then shown, and the stability of motion in an eigen-direction is discussed. The effect of mass distribution on this motion is demonstrated. The example of the freely sliding bar, supported at its ends, is presented in some detail. The stability of orientation at high slip speeds is illustrated through a model of a braked sliding car.

Many of the results in this paper are presented with more detail in Goyal [1989].

Governing Laws

Principle of Maximum Power and Limit Surface

The constitutive law relating the motion of the slider to the friction force and torque is expressed by the limit surface for the slider and the load-motion inequality (essentially the principle of maximum plastic work from classical plasticity) both of which are discussed at length in Goyal [1989] and in Goyal, Ruina, and Papadopoulos [1989]. In short, the limit surface is a closed convex surface in the three dimension space of possible friction loads \( P \equiv [F_x, F_y, M] \). The motion is described by the generalized velocity \( Q \equiv [V_x, V_y, \omega] \) with components which are the translation velocity of a reference point 'O' on the slider, and the angular
velocity of the slider; and the motion vector \( \mathbf{q} \equiv [q_x, q_y, q_\omega] \equiv \mathbf{Q}/|\mathbf{Q}| \). If \( m \) is the mass of the slider, \( r_g \) is its radius of gyration about its center of mass, and \( g \) is the acceleration due to gravity, then all forces are assumed to have been normalized with the reference force \( mg \) (weight of the slider), all moments by the reference moment \( mgr_g \), linear velocities by the reference linear velocity \( \sqrt{g/r_g} \), angular velocities by the reference angular velocity \( \sqrt{g/r_g} \), and time with the reference \( \sqrt{r_g/g} \). \( \mathbf{P} \) and \( \mathbf{Q} \) are related by the load-motion inequality

\[
(\mathbf{P} - \mathbf{P}^*) \cdot \mathbf{Q} \geq 0
\]

which must hold for all \( \mathbf{P}^* \) on or inside the given limit surface. When \( \mathbf{Q} = 0 \), (1) does not restrict \( \mathbf{P} \) so it may be any load on or in the limit surface. Otherwise (1) restricts \( \mathbf{P} \) to be on the limit surface at a point with normal \( \mathbf{q} \). At a vertex (a point or curve of slope discontinuity on the limit surface) we use the word ‘normal’ to describe any vector normal to the vertex if it was locally blunted. At a vertex a range of motions \( \mathbf{q} \) all have a common load \( \mathbf{P} \). If the limit surface is locally flat (appears as a plane or cylinder) \( \mathbf{P} \) is not uniquely determined for a given \( \mathbf{q} \).

Friction laws for which this formalism applies include ordinary isotropic Coulomb friction and also contact mediated by wheels (possibly with bearing friction and/or a bearing ratchet).

Convection of the Limit Surface

With a given pressure distribution on the slip surface of the slider, the shape of the limit surface also depends on the position of the slider if the support plane has inhomogeneous properties, and on the orientation of the slider if it is anisotropic or if the support plane has anisotropic properties.

If the supporting surface is completely isotropic and homogenous (in frictional properties), the limit surface for the slider has a fixed shape that rotates with the slider and is most conveniently defined in a slider fixed axis system. Additionally if the limit surface is a surface of revolution about the \( M \) axis, as it is for an axisymmetric slider, then it does not change at all in either body or space fixed coordinates.

On the other hand, if the slider is completely isotropic and axisymmetric (in support and frictional properties) and the supporting surface is homogenous but anisotropic, the limit surface is fixed in shape and orientation in the frame of the fixed support surface, but not fixed in the frame of the body. An example would be the limit surface for a smooth circular disk sliding on a bed of infinitely fine parallel rollers.

Momentum Balance

The motion of a planar slider is governed by balance of linear and angular momentum, expressed compactly as,

\[
\dot{\mathbf{Q}}\bigg|_{\text{inertial}} = \mathbf{P}^{\text{app}} - \mathbf{P}
\]

where \( \mathbf{P}^{\text{app}} \) is the externally applied load, and \( \dot{\cdot} = d(\cdot)/dt \). We take the \( x \) and \( y \) axis to be fixed in the slider (with origin at ‘O’) so care must be taken when differentiating \( \mathbf{Q} \). By \( \dot{\mathbf{Q}}\bigg|_{\text{inertial}} \equiv [A_x, A_y, \omega] \) is meant a
list of three numbers representing the absolute acceleration and angular acceleration of the slider. On the other hand, it is convenient to differentiate the components of \( Q \) as seen by the sliding body. So we define 
\[
\dot{Q}_{\text{body}} = \left[ V_x, V_y, \omega \right].
\]
The difference between the two is a simple convection term.

\[
\dot{Q}_{\text{body}} = \dot{Q}_{\text{inertial}} - \omega \times Q
\]

or,

\[
\left[ V_x, V_y, \omega \right] = [A_x + \omega V_y, A_y - \omega V_x, \omega]
\]

**Body Fixed Equations Of Motion**

Most of the reasoning which follows assumes that the limit surface, though not necessarily axisymmetric, is of fixed shape and orientation in the slider coordinates. Rather than express rules for the evolution of the limit surface in inertial space, we write the equations of motion in a body fixed frame:

\[
\dot{Q}_{\text{body}} = P^{eff} - P
\]

where we define the effective load \( P^{eff} \equiv P^{app} - \omega \times Q \).

**Uniqueness of Solutions**

The problem of determining the quasi-static motion of a frictional slider often does not have unique solution. That is, if the generalized load on a slider is gradually increased until \( P \) is on the limit surface at a vertex, the incipient motion direction can have a range of values. On the other hand, Mason [1985] states, without explanation, that with the inclusion of inertia slip motion problems have unique solutions. Also, Vosjenli and Eriksen [1985] claim that the conditions of uniqueness are satisfied until final stop (after which the equations of motion obviously cannot be integrated backwards in time in a unique way). However, they only consider sliders for which the frictional load is continuous during the motion. In contrast, we consider sliders for which the frictional force may be discontinuous in time (because of facets on the limit surface).

For given initial conditions and given applied load \( P^{app} \) the right hand side of (2) or (4) is usually fully determined and solution proceeds by direct integration with no ambiguity in the value of \( \dot{Q} \) at any time, and with \( \dot{Q}_{\text{body}} \) being sufficiently smooth in time so that theorems of uniqueness for ordinary differential equations apply. The two possibly exceptional cases are when motion first starts, and when the instantaneous value of \( q \) (or \( Q \)) is normal to a flat region on the limit surface.

**Uniqueness of First Motion**

Assume that at time = 0 a finite load \( P^{app} \) is applied to the slider and that velocity \( Q = 0 \). Either

1) \( P^{app} \) is inside the limit surface then the only consistent solution is \( \dot{Q}_{\text{body}} = 0 \) (imagined small perturbations from no slip decay immediately), and \( P = P^{app} \). Or,
2) \( P^{app} \) is outside the limit surface and some motion must occur. At first motion (= 0+) L'hopital's rule or the mean value theorem can be used to show that \( \dot{Q}_{\text{body}} \) must be parallel to \( Q \). So, from the equation of motion (4) \( P^{eff} - P \) must be parallel to \( Q \). But the load-motion inequality (1) forces \( Q \) to be normal to the limit surface. So \( P^{eff} - P \) must, in turn, be normal to the limit surface at \( P \). Since the limit surface is convex, \( P \) is the (unique) point on the limit surface which is closest to \( P^{eff} \).

Thus the right hand side of (4) is fully determined at first motion.

At first motion \( \omega \times Q \) is of second order so \( P^{eff} \) can be replaced by \( P^{app} \). If \( P^{app} \) is much larger than \( P \)'s on the limit surface \( \dot{Q}_{\text{body}} \) will be nearly parallel to \( P^{eff} \) as one would intuitively expect. If \( P^{app} \) is just outside the limit surface, however, the shape of the limit surface effects the acceleration direction.

**Uniqueness of \( P \) when \( Q \) is Normal to a Facet**

Once slip is underway equation (1) fully determines \( P \) from \( Q \) unless \( Q \) corresponds to a flat region on the limit surface. In \( q \) space flat regions on the limit surface occupy only selected points and thus one might want to neglect them altogether as only occurring with zero probability. But during motion that is not fully constrained, flat sections on the limit surface often attract and/or sustain motions (as will be discussed) and so cannot be neglected.

To understand the evolution of \( P \) on and near a facet, it is useful to look at the components of equation (4) along the direction of motion \( q \) and in a plane perpendicular to it. This yields the following equations as a replacement for (4):

\[
\dot{Q} = (P^{eff} - P) \cdot q \\
Q \ddot{q}_{\text{body}} = \dot{Q}_{\text{tan}} = P^{eff} - P_{\text{tan}}
\]

where \( P_{\text{tan}} = P^{eff} - (P^{eff} \cdot q)q \), and \( P_{\text{tan}} = P - (P \cdot q)q \). Since \( P \cdot q \) is the same for all candidate \( P \) lying on the facet, equation (5) uniquely determines the change in the magnitude of the velocity \( \dot{Q} \).

On and near a facet there are two mutually exclusive possibilities for equation (6), either

1) \( P^{eff} \) is within the infinite cylinder defined by the normals of the facet. Then the only consistent solution is for \( Q \) to remain normal to the facet for finite time with \( q = 0 \). \( P \) is that point on the facet closest to \( P^{eff} \); or

2) \( P^{eff} \) is outside the infinite cylinder defined by the normals of the facet and some tangential motion must occur. \( \ddot{q}_{\text{body}} \neq 0 \) and \( P \) passes off the facet. Now \( P \) can be found by a method like that used for the case of first motion. Analogous to \( Q \) in first motion is \( Q_{\text{tan}} \), the (departing from zero) part of \( Q \) which is tangent to the facet. Also \( \dot{Q}_{\text{tan}}_{\text{body}} = Q \ddot{q}_{\text{body}} \). At first motion L'hopital's rule or the mean value theorem can be used to show that \( \dot{Q}_{\text{tan}}_{\text{body}} \) must be parallel to \( Q_{\text{tan}} \). So, from the equation of motion (6) \( P_{\text{tan}}^{eff} - P_{\text{tan}} \) must be parallel to \( Q_{\text{tan}} \). But the load-motion inequality (1), with the local
geometry of the convex limit surface near the facet, forces \( Q_{\text{tan}} \) to be normal to the boundary of the facet. So \( P_{\text{tan}}^{\text{eff}} - P_{\text{tan}} \) must, in turn, be normal to the boundary of the facet. This enforces that \( P \) be the (unique) point on the limit surface which is closest to \( P^{\text{eff}} \).

Thus the right hand side of (4) is, again, fully determined.

**Determination of \( P \) given \( Q \) and \( P^{\text{app}} \)**

The unique determination of \( P \) given \( Q \) and \( P^{\text{app}} \) is given by the following statement:

*Of all \( P \) consistent, through (1) and the limit surface, with a given \( Q \), the actual \( P \) is that which is closest to \( P^{\text{eff}} \).*

So, assuming the limit surface is known, the right hand side of (4) is always fully determined. At points of frictional force discontinuity the reasoning above leads to well defined jump conditions and thus, we believe, to unique solution (at least integrating forwards in time) of the equations of motion for any given initial condition and applied load. The determination of \( P \) in various cases is shown schematically in figure 1 which shows several cases of \( P^{\text{eff}} \) and \( Q \).

**Eigen-Directions As Final Motions**

Free sliding is the motion of the slider under the action of gravity and dry-friction only. During free sliding, \( P^{\text{app}} = 0 \) in (4), and the body-fixed equation of motion becomes:

\[
\dot{Q}_{\text{body}} = -P - \omega \times Q
\]  

(7)

As the slider comes to rest due to frictional dissipation alone, both \( \omega \) and \( Q \) vanish, so their product may be neglected compared to \( P \) whose magnitude is unaffected by sliding speed. So asymptotically, as the slider approaches zero velocity, its equation of motion (7) becomes:

\[
\dot{Q}_{\text{body}} = -P
\]  

(8)

That is, the convection term introduced in (3) may be neglected (At final motion the space fixed (2) and body fixed (4) equations are identical).

When the slider comes to rest its acceleration is finite and non-zero. Assuming that acceleration is continuous (until it vanishes at final stopping), the mean value theorem or L'Hopital's rule imply that the generalized velocity must be parallel to the generalized acceleration just as the slider comes to rest. Applying this fact to equation (8) leads us to the conclusion that when the slider comes to rest during free sliding, its
motion $Q$ is parallel to the frictional load $P$. This implies that the velocity vector $Q$ comes to rest at only those special points on the limit surface for the slider where the direction of $P$ is parallel to the normal $q$ at that point. We call these special directions in load/motion space, eigen-directions; they include all extrema of $|P|$ on the limit surface.

$$Q \parallel P \text{ at final motion}$$

\hspace{1cm} (9)

**Trajectory on the Limit Surface During Final Motion**

Integration of one of the equations (2,4,7,8) determines the trajectory of the slider in generalized velocity space $Q$, and $P$ is determined as an intermediate variable in this calculation. One can obtain useful information about slip motion, however, by formulating equations for the evolution of $P$.

In order to construct such equations a local description of the limit surface is required. Here we assume sufficient smoothness for a well defined curvature tensor $[k]$ and its inverse $[\rho]$ (O'Neill [1966]) for points on the limit surface. For our purposes these should be thought of as symmetric $3 \times 3$ matrices that have one principal direction orthogonal to the limit surface and two principle directions along the directions of principal curvature of the surface. The eigenvalues of $[\rho]$ are the two principal radii of curvature and a third number arbitrarily taken as 1. If $q$ is the unit normal associated with $P$ and $[\rho]$ is the inverse curvature tensor at that point, we have:

$$\dot{P} = [\rho] \dot{q}$$

\hspace{1cm} (10).

Applying (10) to the body fixed equation of free final motion (8), the normality relation in the friction law, the definition $q = Q/|Q|$, and the fact that when $[\rho]$ acts on vectors tangent to the limit surface the result is a vector tangent to the limit surface:

$$\frac{d}{dt} |P| = -\frac{P_{\text{tan}} [\rho] P_{\text{tan}}}{|P||Q|}$$

\hspace{1cm} (11)

where vector transpose is assumed as needed. Because the limit surface is convex both radii of curvature are non-negative and the tensor $[\rho]$ is positive semi-definite (i.e. $X[\rho]X \geq 0$ for all 3-vectors $X$). The right side of (11) is a negative quantity except at eigen-directions, where $P_{\text{tan}} = 0$ (and also possibly at vertices on the limit surface). Since $|P|$ is the radius of the limit surface we have the geometric description of final motion as being such that the net frictional load decreases in magnitude with time until $P$ reaches an eigen-direction.

**Two Dimensional Motion**

For simplicity consider problems of pure translation, where rotation is not an issue. Such could be the case, for example, if a slider was symmetrically supported with a set of points of identically anisotropic
friction and given no initial rotations. Here $P$ space and $Q$ space are essentially two dimensional and we need not think about the slider's rotation or the convection of the limit surface.

The evolution of $P$ and $Q$ in one time increment is shown in figure 2. The motion is understood using the equation of motion $dQ/dt = -P$, that $Q$ is always normal to the limit curve, and that the limit curve is convex (with the origin in load space inside the limit curve). The evolution proceeds as $P$ decreases in magnitude and $Q$ also decreases in magnitude (5).

**Eigen-directions in Two Dimensional Slip**

Figure 3 shows three examples of eigen-directions for two dimensional motion (or motion of an axisymmetric object). As one can easily verify from the three cases drawn in figure 3, small deviations from motion in an eigen-direction either grow or decay depending on the radius and curvature of the limit surface in the neighborhood of the eigen direction. That is $|P - P_{eigen}|$ and $|q - q_{eigen}|$ either grow or decay as time progresses.

The result from (11) that $|P|$ decreases in time implies (since the set of $P$ with constant magnitude is a circle) that the directional stability of an eigen-direction is determined by the radius of curvature $\rho_c$ of the limit surface and the magnitude of the frictional load $|P|$ [Goyal [1989]. In summary:

1. $\rho_c > |P| \Rightarrow |P|$ is a local minimum and $q$ is locally attracted to the eigen-direction. Many initial conditions will have this eigen-direction as a final motion.
2. $\rho_c < |P| \Rightarrow |P|$ is a local maximum and $q$ is locally repelled by the eigen-direction. Only special initial conditions will have this final motion.
3. $\rho_c = |P| \Rightarrow q$ is neither repelled nor attracted by its neighboring eigen-direction. To first order, there is a small neighborhood of eigen-directions.

So the critical condition for directional stability of an eigen-direction is that a circle centered at the origin of load space has second order tangency with the limit surface:

$$\rho_c = |P|.$$  \hspace{1cm} (12)

**Axisymmetric Sliders Have Two Dimensional Behavior**

The reasoning associated with figure 2 is also applicable to axisymmetric bodies. In this case $P$ in equation (1) is fully represented by a generating curve of the axisymmetric limit surface. The vertical axis then represents moment and rotation rate, the horizontal axis represents translation and force in the initial unforced direction of motion.

**Eigen-directions for Axisymmetric Sliders**
The center of mass of a freely sliding axisymmetric body always travels in a straight line in inertial space \textit{Vegynli and Eriksen} [1985]. If \( q \) is constant (in space fixed coordinates), the locus of instantaneous centers of rotation is a straight line in physical space and a circle on the body. So constant \( q \) motion is rolling of a circle attached to the slider on a line fixed in inertial space. This is the final constant \( q \) eigen-motion of an axisymmetric slider. The radius of the rolling circle is determined by the eigen-direction \( q \). Final motions for a uniformly supported ring and a uniformly supported disk, both with isotropic friction, are found by \textit{Ishlinskii, Sokolov, and Chernousko} [1981] and by \textit{Vegynli and Eriksen} [1985]. Though our results generalize the results in these papers, we consider the same two examples for illustration.

**Hollow Ring With Isotropic Friction:** For the uniformly supported ring of isotropic support (unit radius, unit weight and unit coefficient of friction), a sliding Hula Hoop, the equations parameterizing the generating curve of its limit surface can be given as:

\[
F_y(r_c) = \frac{1}{\pi} \int_0^\pi \frac{\cos \theta - r_c}{\sqrt{1 + r_c^2 - 2r_c \cos \theta}} d\theta, \quad M(r_c) = \frac{1}{\pi} \int_0^\pi \frac{1 - r_c \cos \theta}{\sqrt{1 + r_c^2 - 2r_c \cos \theta}} d\theta
\]

where motion is in the \( y \) direction. This curve, parameterized through the radius of the circle of centers of rotation \( r_c \) for \( 0 < r_c < \infty \), is shown by the dotted curve in figure 4. The attracting eigen-direction for the ring, as shown in figure 4 (\( P = [0, 2/\pi, 2/\pi] \) and \( q = [0, 1/\sqrt{2}, 1/\sqrt{2}] \)), is rotation about a point on the ring itself. Curiously, the generating curve for the limit surface of the ring is symmetric about a 45° line on figure 4.

**Disk of Isotropic Friction:** For the uniformly supported disk of isotropic support (unit radius, unit weight, radius of gyration \( r_g = 1/\sqrt{2} \), and unit coefficient of friction) the generating curve is shown in figure 5 where motion is again in the \( y \) direction (\textit{Goyal} [1989]). The attracting motion for the disk then, depicted on the dotted generating curve in figure 5 (\( P \simeq [0, 0.616, 0.667] \) and \( q \simeq [0, 0.678, 0.735] \)), is rotation about points on a circle of radius \( \simeq 0.653 \) drawn on the disk (\textit{Ishlinskii, Sokolov, and Chernousko} [1981] report the radius of this circle incorrectly as 0.71).

For both the ring and the disk, pure rotation about the center and pure translations are unstable eigen-directions (i.e. small perturbations from these motions grow in time) and they persist only if started precisely.

**Dependence of Eigen-Directions on Mass Distribution**

As mentioned earlier, the radius of gyration \( r_g \) of the slider is used as the reference length for nondimensionalization of moment \( M \) and velocity \( V \). Hence the shape of the limit surface for a slider with a fixed contact pressure distribution can be altered by changing its radius of gyration, i.e. by altering its mass distribution. For a fixed contact pressure distribution, increasing \( r_g \) (distributing the mass further away
from the center) effectively compresses the limit surface along the \( M \) axis, and decreasing \( r_g \) (concentrating the mass closer to the center) stretches it. For either of these cases the limit surface remains fixed along the force axes, but suffers a change in aspect ratio (shape). This can lead to changed eigen-directions. Also eigen-directions that are preserved by the distortion of the limit surface (on the \( M \) axis or the \( F \) axis) can have altered stability and hence changed 'free sliding' behavior.

In particular, for the uniformly supported ring of isotropic support, we might imagine gluing a massless board on top and distributing mass at an arbitrary radius of gyration \( r_g \). Assuming contact at radius=1 and limit surface parameterized by equations (13), it can be shown that (Goyal [1989]):

1) For \( r_g < 1/\sqrt{2} \), all initial motions (except pure rotation) of the freely sliding ring end as pure translations.

2) For \( r_g > \sqrt{2} \), all initial motions (except pure translations) of the ring end as pure rotations about its center.

3) For \( 1/\sqrt{2} \leq r_g \leq \sqrt{2} \), the final attracting motion depends on the value of \( r_g \) and ranges from rotations about the center to pure translation.

Hence any desired radius of 'rolling like motion' can be made its final attracting motion by choosing an appropriate mass distribution.

A similar result holds for the uniformly supported disk (Goyal [1989]). By varying its radius of gyration \( r_g \) between \( 1/2 \) and \( \sqrt{2/3} \) and keeping its support pressure distribution unaltered, any desired radius of rolling can be made its final attracting motion. Figures 4 and 5 show the original generating curves for the ring and the disk respectively with their shapes at the bounding values of \( r_g \). For both sliders, if \( r_g \) is sufficiently large, rotation is the only stable eigen-direction. If the radius of gyration is small, translation is the only stable eigen-direction. These latter properties hold for all axisymmetric sliders with smooth, facetless limit surfaces.

**Three Degree of Freedom Motion**

With three degrees of freedom (two translations and a rotation) the situation is somewhat more complex, except in the special case of axisymmetry just discussed. \( P \) in (1) requires a 3-dimensional representation and (4) contains a convective term.

But at final motion the convective term in (4) can be neglected and the motion can again be simply pictured. The direction of \( \dot{Q}_{body} \) depends only on \( P \), \( q \), and the local shape of the limit surface, and not on the magnitude of \( Q \). So the final trajectories in \( P \) and \( q \) space are intrinsic to the limit surface.

As for the two dimensional case, three dimensional geometry and the equations of motion for the three dimensional limit surface show that if \( P \) is an eigen-direction, with associated principal radii of curvature \( \rho_i \).
and \( \rho_2 \) (in load space), then:

1. \( \rho_1, \rho_2 > |P| \) implies that \( |P| \) is a local minimum and the eigen-direction attracts all motions in its local vicinity. \( P \) is a stable eigen-direction.

2. \( \rho_1 \) or \( \rho_2 < |P| \) implies that \( |P| \) is a local maximum (for some tangent directions on the limit surface) and repels all motions in its vicinity. \( P \) is an unstable eigen-direction.

3. \( \rho_1 = \rho_2 = |P| \) implies that \( |P| \) is stationary and motions are neither attracted or repelled (to first order) in its local vicinity. \( P \) is a neutrally stable eigen-direction.

So the critical condition for directional stability of an eigen-direction is that a sphere of radius \( |P| \) centered at the origin of load space lie locally inside the limit surface.

This directly implies that eigen-directions at vertices on the limit surface are completely unstable. And eigen-directions on flat regions of the limit surface are stable. The fact that the limit surface is closed, convex and encloses the origin, implies that it has to have at least two eigen-directions, the minimum and the maximum load respectively. The minimum load is either a stable or a neutrally stable eigen-direction. Similarly, the maximum load is either an unstable or a neutrally stable eigen-direction.

As noted with regard to axisymmetric sliders, the mass distribution effects the eigen-directions and their stability. For all sliders, if mass is broadly distributed compared to the contact region pure rotation will become a stable eigen-direction (unless the limit surface has a vertex on the \( M \) axis, in which case something very close to pure rotation will be a stable eigen-direction). If mass is quite central, pure translation will become a stable eigen direction (unless the limit surface has a vertex on the \( F \) plane, in which case something very close to pure translation will be a stable eigen-direction).

**Bead Analogy**

The motion of \( P \) on the limit surface during free slip is partially analogous to the motion of a tiny massless bead moving on a viscously coated, closed, convex shell in the physical shape of the limit surface. This bead is attracted towards the center of the shell by a spring. The equilibrium positions for the bead on this surface are those where the direction of the spring force (direction of \(-P\)) is parallel to the normal of the surface (the direction of \( Q \)), so that there is no component of the spring force in the tangent plane to the surface trying to move the bead along it. These equilibrium positions, local extrema of the radius vector from the center to the surface of the shell, are eigen-directions. Additionally, local minimas are stable equilibrium positions for the bead and maximas are unstable equilibrium positions.

**Rotation About Points of Isotropic Support**

Investigators like *Jellett* [1872], *Prescott* [1923] and *MacMillan* [1936] have noted that sliders with
isotropic friction show a propensity towards rotating about points of support. In terms of the limit surface formalism, we can explain this phenomenon roughly as follows:

1) Point supports on a slider with isotropic friction lead to flat regions on its limit surface that might occupy a substantial area of the total surface. Hence, by increasing any applied load until it lies on the limit surface there is high probability that the corresponding first motion of the slider will be a rotation about a point of support. This is exemplified by the limit surface of the symmetrically supported bar of figure 6.

2) Since point supports lead to flat facets and the corresponding principal radii of curvature are \( \rho_1 = \rho_2 = \infty \), an eigen-direction on the facet must be stable. For the symmetrically supported bar below, rotation about one of the points of support is the final attracting motion for all initial motions except pure rotations and translations. However, all flat regions need not have an eigen-direction as can be seen from the example of the asymmetrically supported bar discussed later.

3) From manipulation of equation (6) it can also be shown that, besides pure rotations and translations, the only motion direction \( \mathbf{q} \) that can be sustained for a finite amount of time corresponds to the normal of a flat region on the limit surface. Motions about points of isotropic support satisfy this criterion and can in fact be sustained for a finite time. If such motion is an eigen-motion then, if it occurs at all, it is sustained until the slider comes to rest.

**Free Sliding of Symmetrically Supported Bar**

To verify and illustrate the above conclusions, we present results of the numerical simulation of the free sliding of a symmetrically supported bar with isotropic friction. The bar has unit weight with point masses concentrated at its ends, half length of the bar is 1, its radius of gyration \( r_g = 1 \), and the coefficient of friction is 1. The bar and its limit surface are presented in figure 6. Motion of similar objects was studied numerically by Ishlinskii, Sokolov, and Chernousko [1981] and analytically by Wittenburg [1970].

From the limit surface of the bar (figure 6), one can see that instantaneous rotations about its points of support are final attracting motions for all initial motions of the slider except for pure rotations and translations. Also, the slider rotates about a point of support for a finite amount of time before it comes to rest, for a time period which depends on initial conditions. The facet on the limit surface generally leads to discontinuity in the frictional load \( P \) during the 'free sliding'. In general, the load jumps from the edge of the flat facet to some point on its interior.

'Free sliding' of the bar was numerically simulated, and the results depicted on the unit motion sphere of figure 7. This figure shows the evolution of motion as seen in a bar fixed axes system. The light curves on the unit motion sphere depict the flow field, along which various motions of almost zero magnitude (governed by (8)) approach the stable eigen-direction. The dark line shows the trajectory of a finite non-zero motion.
of the bar (governed by (4)) as it approaches sleep along the stable eigen-direction \( \mathbf{P} = [0.5, 0, 0.5] \) and associated \( \mathbf{q} = [1/\sqrt{2}, 0, 1/\sqrt{2}] \). Not only do all initial motions come to rest along a stable eigen-direction, but also their direction of final approach towards this \( \mathbf{q} \) is unique. It corresponds to a slight translation along the bar superposed on the rotation about one point. Its apparent physical origin is the centrifugal pull of the last moving point on the point which is about to be the center of rotation.

Other Examples of Free Sliding With Point Supports

Flat regions on the limit surface need not represent an eigen-direction. Consider a variation on the bar mentioned in the previous example that is supported by friction strengths of magnitude 2 and 1, at distances 1 and 2 respectively on either side of its center of mass. The mass distribution of the bar is such that its radius of gyration \( r_g = 4 \) (note that the mass is not concentrated at the points of support). Then the section of its limit surface on the \([F_x, M]\) plane is shown in figure 8. As can be seen from this figure only one set of flat regions have a stable eigen-direction, that corresponds to instantaneous rotation about the stronger point of support. Rotation about the weaker point of support is no more an eigen-direction and this particular motion cannot even be sustained for finite time.

Another interesting aspect of rotation about a point of support is that it can in some circumstances be sustained for a finite time, even if not associated with an eigen-direction and final motion. This can be illustrated with the example of the strangely supported plate below of figure 9. The plate has all its mass \( m \) concentrated very close to 'O', its center of mass. It is supported at various points with spatially non-uniform isotropic friction (the center of the contact pressure distribution coincides with the center of mass), but only at two points, labeled \( a \) and \( b \) in the figure, is the coefficient of friction non-zero. Also the frictional strength at \( b \) is larger than at \( a \). For this plate, rotation about \( a \) is not an eigen-direction, although such a motion can be sustained for a finite amount of time. Depending on the angular velocity \( \omega \) with which the plate is rotating about \( a \), force balance can be attained between the friction forces \( f_a \) and \( f_b \), the centrifugal force \( m r a^2 \) due to the rotating point mass \( m \), and other inertial forces, such that this motion is sustained for a while. But as the plate slows down due to frictional dissipation, \( \omega \) and hence \( m r a^2 \) decreases in magnitude and eventually a value of \( \omega \) is attained when \( f_a \) is no longer enough to counteract the other forces and the plate breaks loose at \( a \).

Effect of Convective Terms on Orientation Stability

It is well known in the automotive industry, though possibly counter-intuitive, that if the rear wheels are locked while the front wheels roll freely the vehicle will lose directional stability (Wong [1978]). Keeping this phenomenon in mind, we consider the limit surface description of an elementary model of a car with locked rear wheels.

We collapse the car laterally (making it effectively unidimensional) and represent it as a bar supported
at its ends, the front end being supported by a wheel with its axle perpendicular to the car, and the back end by a point of isotropic support (a locked wheel), each end being unit distance away from the center of the car. Equal point masses are located at each end of the car and their coefficients of friction \( \mu \) are equal. Both the car and its limit surface are shown in figure 10. The limit surface for the car is an elliptical cylinder and it is rather singular in that it is made up entirely of vertices and flat (at least in one direction) regions. The elliptical facets correspond to rotation about the point of isotropic support (the locked rear wheel), the sides correspond to pure rolling of the front wheel (COR's with the coordinate \( y_0 = 1 \)), and each point on the elliptical edge has a set of CORs lying on a line (specific to that point) passing through the point of isotropic support. Observe also that the limit surface has only one plane of symmetry, the \( M - F_x \) plane.

It can be seen that of the many eigen-directions there are four which are stable. These are forward and backward translations of the car (in the direction of the car itself) and clockwise and counter-clockwise rotations about the point of isotropic support. Thus at final motion the car is necessarily moving either frontwards, backwards or is rotating about its braked wheel.

One can also discuss directional stability at finite velocities. At all velocities straight ahead motion and straight backwards motion persist till the car stops, if the car is started precisely with these motions. But if small perturbations are imposed the directional stability is different for the two cases. In particular, the symmetry of the limit surface for forwards translation (\( q = [0, 1, 0] \)) and backwards translation (\( q = [0, -1, 0] \)) is not manifested by identical equations of motion for the two cases because of the convective term. Calculation shows (Appendix) that forward translation is directionally unstable at speeds of \( \sqrt{\mu} \) and above, and stable at less than \( \sqrt{\mu} \). Backwards translation (or equivalently forwards translation with front wheels locked and rear wheels free) is always directionally stable.

**Free Sliding of Sliders With a Single Coefficient of Isotropic Friction**

For reference we here summarize some properties of free slip for a slider that has a single coefficient of friction acting at each of the contact points, and has all mass concentrated in the slip plane. Most have been mentioned by other authors and can be directly demonstrated without the use of the limit surface description. Most of them also do not depend on the pressure distribution and so are insensitive to the large variations in pressure distribution that one expects during slip of real nearly-flat hard objects in contact.

\(|Q| \) **Decreases in Time:** \( Q \cdot Q \) is proportional to the kinetic energy which is naturally expected to decrease in time. Direct application of (1) and (4), with the fact that the limit surface is convex and encloses the origin (so \( P \cdot Q < 0 \), shows that \( Q \cdot Q < 0 \)). This is true, of course, for all sliders and does not depend on the isotropy of friction.

\(|P| \) **Sometimes Decreases in Time:** When the convection term in (3) can be neglected, \( |P| \) is non-increasing. The convection terms are zero for pure translation, pure rotation, and asymptotically as motion
comes to a stop.

**ω Decreases in Time:** The limit surfaces under discussion intersect the $x$-$y$ plane at a circle (independent of the symmetry of the pressure distribution). The normals to the limit surface on this circle lie in the $x$-$y$ plane. Since the limit surface is convex, all $Q$ with positive $\omega$ correspond to $P$ in the upper half space where $M$ is positive and, by equation (4) $\dot{\omega} < 0$ (note that the convection terms make no contribution to $\dot{\omega}$).

Note that even if rotation corresponds to an unstable eigen-direction and that small perturbations from pure rotation grow (as seen by the changes in $P$ and $q$), the absolute rotation rate is always decreasing. When the ring described earlier is started in nearly pure rotation and ends by rotating and translating at the same rate, the rotation rate is always decreasing (and the translation rate decreases even faster).

When anisotropic friction is allowed it is possible not just for the direction in motion space to lead to increase relative rotation, but for the absolute rotation rate to increase in time. The braked car considered above is an example.

**Pure Rotation and pure translation are Eigen-Directions:** Sliders with uniform coefficient of friction and identical centers of pressure and gravity have horizontal limit surfaces on the $M$ axis and intersect the $x$-$y$ plane at a circle with the tangent to the limit surface being vertical at the intersection. Both pure rotation and pure translation are eigen directions.

Additionally the convective term in equation (2) is identically zero for these motions so they persist for finite time once initiated. An object set in translation will continue translating in a straight line until it stops. An object set in pure rotation will rotate without translation until it stops.

**An Axisymmetric Object Moves in a Straight Line:** A non axisymmetric body does not have to travel in a straight line, however. The center of gravity of the sliding dumbbell does not travel on a straight line if the rotation rate is non-zero.

**Motion Planning**

The details of the pressure distribution between hard nearly flat objects is notoriously unpredictable. Generically one expects support to be governed by three point-like contacts of unknown location and one expects a six-faceted limit surface with facets in unknown orientations. So the overall friction relation is also highly indeterminate, as *Mason and Salisbury* [1985] and *Peshkin* [1986] have emphasized. One approach to control is to overwhelm the indeterminate friction forces with large accurately controlled externally applied loads.

Understanding the transition from indeterminacy at small applied loads to determinacy at high loads might be enhanced by reference to the earlier discussion of uniqueness. During slip the friction load is that
point on the limit surface which is closest to the applied load. If the applied load is not much larger than the frictional resistance, there is high probability of the closest point on the limit surface being on a facet (if the limit surface has facets) or other non-spherical feature of the limit surface and for the first motion to be that corresponding to the normal at that point. If the applied load is large, however, $Q$ will be nearly parallel to the load, and therefore less dependent on the details of the frictional interface.

**Conclusions**

The limit surface description of the load-motion relation for planar sliders is a useful tool for understanding slip and its control for both slipping and wheeled objects. The frictional load during dynamic slip is unambiguous, even if the friction law is in some senses multivalued. When sliders come to rest during free slip they do so with special motions called eigen-directions, where $P$ is parallel to $q$ on the limit surface. For motions of very small magnitude the 'stability' of eigen-directions is governed by the principle radii of curvature and the load vector at the eigen-direction. The change in stability aspects of eigen-directions for motions of higher magnitude, due to non-symmetries of the governing equations is illustrated by a partially braked car. The relation between mass distribution and eigen-directions is such that with most objects, if the mass is sufficiently spread compared to the contact region, the object will have final motion which is pure rotation about the center of mass, and if the mass is sufficiently central it will have final motion that is pure translation. The tendency of objects to rotate about points of support can be explained in terms of the finite surface area for flat regions (corresponding to point supports) on the limit surface and their propensity to attract and sustain motions for a finite amount of time.

Appendix: Analysis of Braked Car

Except for the elliptical caps the limit surface for the braked car is given in terms of $q_x, q_y, q_\omega$ and the parameter $A$ as:

$$F_x = \frac{\mu(q_x + q_\omega)}{2\sqrt{1 + 2q_x q_\omega}} + \frac{\mu A}{2}$$

$$F_y = \frac{\mu q_y}{2\sqrt{1 + 2q_x q_\omega}}$$

$$M = \frac{\mu(q_x + q_\omega)}{2\sqrt{1 + 2q_x q_\omega}} - \frac{\mu A}{2} \quad (A1)$$

where the value of $A$ is given by the following.

1) If $q_x = q_\omega \Rightarrow -1 \leq A \leq 1$, i.e. the frictional load is on the sides of the cylinder. (However a unique value can be found from dynamical considerations, given as $A = |Q|^2 q_y q_\omega/\mu$).

2) If $q_x > q_\omega \Rightarrow A = 1$ (one elliptical cap).

3) If $q_x < q_\omega \Rightarrow A = -1$ (the other elliptical cap).

To investigate the stability of forward and backward translation $[q_x, q_y, q_\omega] = [0, \pm 1, 0]$ we manipulate (4) and (A1) to get:

$$|Q| \dot{\mathbf{q}}_{\text{body}} = \begin{bmatrix} -\frac{\mu q_y(1-q_x^2)}{2\sqrt{1+2q_x q_\omega}} + \frac{\mu}{2} A(q_x^2 - q_x q_\omega - 1) + |Q|^2 q_y q_\omega \\ \frac{\mu q_x q_y}{\sqrt{1+2q_x q_\omega}} + \frac{\mu}{2} A(q_y - q_\omega) - |Q|^2 q_x q_\omega \\ -\frac{\mu q_y(1-2q_x^2)}{2\sqrt{1+2q_x q_\omega}} + \frac{\mu}{2} A(q_\omega q_x - q_\omega^2 + 1) \end{bmatrix} \quad (A2)$$

The only perturbations from straight motion that do not decay immediately are those where the free front wheel keeps rolling and the locked rear wheel acquires a small sideways motion. This group of perturbations is given by $q_x = q_\omega \ll 1, q_y \approx \pm 1$, and consequently equation (A2) reduces to:

$$|Q| \dot{\mathbf{q}}_{\text{body}} \approx \left( \frac{|Q|^2}{2} - \frac{\mu q_y}{2} \right) \begin{bmatrix} q_x q_y \\ -2q_x^2 \\ q_\omega q_y \end{bmatrix} \quad (A3)$$

Examination of (A3) shows that for all velocity magnitudes $|Q|$ of the bar, $q = [0, -1, 0]$ is an attracting motion i.e. motions in its vicinity are attracted to it. But $q = [0, 1, 0]$ is an attracter only for $|Q| < \sqrt{\mu}$, for higher velocity magnitudes all perturbations are attracted to $q = [0, -1, 0]$.

Redimensionalizing and using a friction coefficient $\mu = 1$, gravitational acceleration $g = 9.8m/s^2$, and radius of gyration $r_g = 1m$ (for a 2m car), we get a critical speed of $v = \sqrt{\mu g r_g} \approx 11.3km/hr$. At speeds less than this, rear braking is safe. In fact a braked car is stable with its front wheels locked for much the same reason that the feather end of an arrow stably follows the head in flight.

The friction force is non-zero only at two points of support \(a\) and \(b\) and \(f_b > f_a\). Rotation about \(a\) is not an eigen-direction, although this rotation can be sustained for a finite amount of time at finite rotation rates.
Figure 10. Simple model of a car with locked rear wheels (bar supported at its ends by an ideal wheel and a point of isotropic support) and its limit surface (an elliptical cylinder). This limit surface has only one plane of symmetry, the $F_x - M$ plane. From a first order stability analysis of this surface it can be seen that forward and backward translations of the bar (in the direction of the bar itself), and clockwise and counter-clockwise rotations about the point of isotropic support are all stable eigen-directions. For high velocities, forward translation is unstable even though it is a stable eigen direction.
